In sowing a fine green plat, there is a difficulty in getting good seed; it ought not to be such as is taken out of the hay-loft without distinction; for that seed shooting too high and making large stalks, the lower part will be naked and bare; and although it be mowed ever so often, it will never make handsome Grass; but, on the contrary, will come to nothing but tufts of weeds and Quick-grass, very little better than that of the common fields.

If walks or plats be made by sowing, the best way is to procure the seed from those pastures where the Grass is naturally fine and clear, or else the trouble of keeping it from spiry and benty Grass will be very great, and it will scarce ever look handsome.

In order to sow Grass-seed, the ground must be first dug or broken up with a spade; and when it has been dressed and laid even, it must be very finely raked over, and all the clods and stones taken off, and covered over an inch thick with good mould, to facilitate the growth of the seed; this being done, the seed is to be sown pretty thick, that it may come up close and short; and it must be raked over again to bury and cover the seed, that if the weather should happen to be windy, it may not be blown away.

As to the season of sowing Grass, the middle or latter end of August is a good time, because the seed naturally requires nothing but moisture to make it grow: if be not sown till the latter end of February, or the beginning of March, if the weather proves dry, it will not so soon make the walks or quarters green. It is also best to sow it in a mild day, and inclining to rain; for that, by sinking down the seed in the earth, will cause it to shoot the sooner. But where Grass is sown in gardens, either for lawns or walks, there should always be a good quantity of the White Trefoil or Dutch Clover sown with it, for this will make a fine turf much sooner than any other sown Grass, and will continue a better verdure than any of the Grass tribe.

After the seed is well come up, and the Grass is very thick and of a beautiful green, it will require a constant care to keep it in order: this consists in mowing the Grass often, for the oftener it is mowed, the thicker and handsomer it grows; it must also be rolled with a cylinder or roller of wood, to level it as much as possible.

If Grass be neglected, it will run into Quick-grass and weeds; and if it does so, there is no way to recover it, but either by sowing it, or laying it over again, and that once in every two years; but if the ground be well cleared from the roots of strong weeds, and the turf be taken from a fine level common, it will continue handsome for several years, provided it be well kept.

In order to keep Grass-plats or walks handsome and in good order, in autumn you may sow some fresh seed over any places that are not well filled, or where the Grass is dead, to renew and furnish them again; but there is nothing which improves Grass so much as constant rolling and polling it, to destroy wormcasts, and thereby the turf is rendered fine.

It is a general practice when turf is laid in gardens, to cover the surface of the ground under the turf, either with sand or very poor earth; the design of this is to keep the Grass fine, by preventing its growing too rank. This is proper enough for very rich ground, but is not so for such land as is but middling or poor; for when this is practised in such places, the Grass will soon wear out, and decay in patches.

When turf is taken from a common or down, there should be regard had to the cleanness of it, and not to take such as is full of weeds: for it will be a very tedious piece of work, to weed them out after the turf is laid; and unless this is done, the Grass will never appear handsome.

Where turf is designed to remain for years without renewing, there should be dressing laid upon it every other year, either of very rotten dung, ashes, or, where it can be easily procured, very rotten tan, is a good dressing for Grass; but these dressings should be laid on early in winter, that the rain may wash them into the ground, before the drought of the spring comes on, otherwise they will occasion the Grass to burn when the warmth of summer begins. Where Grass is so dressed, and kept well rolled and mowed, it may be kept very beautiful for many years; but where it is not dressed or fed with sheep, it will rarely continue handsome more than eight or ten years.

GRATIOLOA. Lin. Gen. Plant. 27. Raii Meth. Plant. 90. Digitalis. Tourn. Inst. R. H. 165. Hedge Hyssop.

The CHARACTERS are,

The flower hath a permanent empalement, which is cut into five parts; it hath one petal of the grinning kind, with a tube longer than the empalement, cut at the top into four small segments, the upper being broader and indented at the end where it is reflexed; the other three are erect and equal. It hath five awl-shaped stamina, three of which are shorter than the petal, and sterile; the other two are longer, and adhere to the tube of the petal; these are fruitful in male dust; they are terminated by roundish summits. In the center is situated a conical germen, supporting an erect style, crowned by a stigma with two lips, which close after being fecundated. The germen afterwards becomes an oval capsule ending in a point, having two cells which are filled with small seeds.

This genus of plants is ranged in the first section of Linnaeus's second class, intitled Diandria Monogynia, which includes those plants whose flowers have but two stamina and one style, for he does not esteem the three barren stamina as worthy notice.

The SPECIES are,

1. GRATIOLOA (*Officinalis*) floribus pedunculatis, foliis lanceolatis serratis. Lin. Mat. Med. 18. Hedge Hyssop with flowers standing on foot-stalks, and spear-shaped leaves. Digitalis minima Gratiolata dicta. Mor. Hist. 2. 479. Least Foxglove, called Gratiola.
2. GRATIOLOA (*Virginiana*) foliis lanceolatis obtusis subdentatis. Flor. Virg. 6. Hedge Hyssop with obtuse indented leaves.
3. GRATIOLOA (*Peruviana*) floribus subsessilibus. Lin. Sp. Plant. 17. Hedge Hyssop with flowers sitting close to the branches. Gratiola latiore folio flore albo. Feuill. Peruv.

The first sort grows naturally on the Alps, and other mountainous parts of Europe. This hath a thick, fleshy, fibrous, creeping root, which propagates very much when planted in a proper soil and situation, from which arise several upright square stalks, near a foot high, garnished with narrow spear-shaped leaves placed opposite; the flowers are produced on the side of the stalks at each joint, they are shaped like those of the Foxglove, but are small, and of a pale yellowish colour. These appear in July, but are seldom succeeded by seeds in England.

It is easily propagated by parting of the roots; the best time to do this is in the autumn, when the stalks decay; the plants should have a moist soil and a shady situation, in which they will thrive exceedingly; but in dry ground they often decay in summer, unless they are plentifully watered.

This

This stands in the list of medicinal plants, but is very rarely used in England, though it is recommended by some good writers as a purger of serous and cholic humours.

The second sort grows naturally in North America, from whence I received the seeds. This grows naturally in moist places, where it rises more than a foot high, but in England I have not seen it more than eight inches; the leaves are blunt, and indented at their extremities; the flowers are white, and come out from the side of the stalks, like those of the other, but are not succeeded by seeds here. It may be propagated in the same manner as the first sort, and requires the same treatment.

The seeds of the third sort were sent me from Carthage, where it was found growing naturally in places where there had been standing waters, which were then dried up; this plant grew about nine inches high, with a weak stalk, and the leaves placed opposite; they were about three quarters of an inch long, and half an inch broad, sawed on their edges; the flowers came out single on each side the stalk; they were white, and much smaller than those of the first sort, but were not succeeded by seeds, so the plant was lost here.

GRAVEL and **Grafs** are naturally ornaments to a country-seat, and the glory of the English gardens, and things in which we excel all other nations, as France, Holland, Flanders, &c.

There are different sorts of Gravel, but for those who can conveniently have it, I approve of that Gravel on Blackheath, as preferable to most that we have in England; it consisting of smooth even pebbles, which, when mixed with a due quantity of loam, will bind exceeding close, and look very beautiful, and continue handsome longer than any other sort of Gravel which I have yet seen.

Some recommend a sort of iron-mould Gravel, or Gravel with a little binding loam amongst it, than which nothing, they say, binds better when it is dry; but in wet weather it is apt to stick to the heels of one's shoes, and will never appear handsome.

Sometimes loam is mixed with Gravel that is over sandy or sharp, which must be very well blended together, and let lie in heaps, after which it will bind like a rock.

There are many kinds of Gravel which do not bind, and thereby cause a continual trouble of rolling, to little or no purpose; as for such,

If the Gravel be loose or sandy, you should take one load of strong loam, to two or three of Gravel, and so cast them well together, and turn this mixture over three or four times, that they may be well blended together; if this is done in proper proportion, it will bind well, and not stick to the feet in wet weather.

There are many different opinions about the choice of Gravel; some are for having the Gravel as white as possible, and in order to make the walks more so, they roll them well with stone rollers, which are often hewn by the masons, that they may add a whiteness to the walks; but this renders it very troublesome to the eyes, by reflecting the rays of light so strongly, therefore this should ever be avoided; and such Gravel as will lie smooth, and reflect the least, should be preferred.

Some screen the Gravel too fine, which is an error; for if it be cast into a round heap, and the great stones only raked off, it will be the better.

Some are apt to lay Gravel-walks too round, but this is likewise an error, because they are not so good to walk upon, and besides, it makes them look narrow; one inch rise is enough in a crown for a walk of five feet; and it will be sufficient, if a walk be ten feet wide, that it lies two inches higher in the middle than it does on each side; if fifteen feet, three inches; twenty feet, four; and so in proportion.

For the depth of Gravel-walks, six or eight inches may do well enough, but a foot thickness will be sufficient for any; but then there should always be a depth of rubbish laid under the Gravel, especially if the

ground is wet; in which case there cannot be too much care to fill the bottom of the walks with large stones, flints, brick rubbish, chalk, or any other materials which can be best procured, which will drain off the moisture from the Gravel, and prevent its being poachy in wet weather; but as it may be difficult in some places to procure a sufficient quantity of these materials to lay in the bottom of the walks, so there may be a bed of Heath, or Furze, which ever can be procured at the least expence, laid under the Gravel to keep it dry: and if either of these are used green, they will lie a long time, as they will be covered from air, and these will prevent the Gravel from getting down into the clay, and will always keep the Gravel dry; and where there is not this precaution in the first laying of the Gravel upon clay, the water being detained by the clay, will cause the Gravel to be poachy whenever there is much rain.

In making of Gravel-walks, there must be great regard had to the level of the ground, so as to lay the walks with easy descents toward the low parts of the ground, that the wet may be drained off easily; for when this is omitted, the water will lie upon the walks a considerable time after hard rains, which will render them unfit for use, especially when the ground is naturally wet or strong; but where the ground is level, and there are no declivities to carry off the wet, it will be proper to have sink-stones laid by the sides of the walks, at convenient distances, to let off the wet; and where the ground is naturally dry, that the water will soon soak away, the drains of the sink-stones may be contrived so as to convey the water in fesspools, from which the water will soak away in a short time; but in wet land there should be under-ground drains, to convey the wet off, either into ponds, ditches, or the nearest place to receive it; for where this is not well provided for, the walks will never be so handsome or so useful.

The month of March is the properest time for laying Gravel; it is not prudent to do it sooner, or to lay walks in any of the winter months before that time.

Some indeed turn up Gravel-walks in ridges in December, in order to kill the weeds; but this is very wrong, for besides that it deprives them of the benefit of them all the winter, it does not answer the end for which it is done, but rather the contrary; for though it does kill the weeds for the present, yet it adds a fertility to them, as to the great future increase of both them and Grafs.

If constant rolling them after the rains and frost will not effectually kill the weeds and moss, you should turn the walks in March, and lay them down at the same time.

In order to destroy worms that spoil the beauty of Gravel, or Grafs-walks, some recommended the watering them well with water, in which Walnut-tree leaves have been steeped, and made very bitter, especially those places most annoyed with them; and this they say, as soon as it reaches them, will make them come out hastily, so that they may be gathered; but if, in the first laying of the walks, there is a good bed of lime rubbish laid in the bottom, it is the most effectual method to keep out the worms, for they do not care to harbour near lime.

GREEN-HOUSE, or **Conservatory**.

As of late years there have been great quantities of curious exotic plants introduced into the English gardens, so the number of Green-houses, or Conservatories, have increased; and not only a greater skill in the management and ordering of these plants has increased therewith, but also a greater knowledge of the structure and contrivance of these places, so as to render them both useful and ornamental, hath been acquired; and since there are many particulars to be observed in the construction of these houses, whereby they will be greatly improved, I thought it necessary not only to give the best instructions for this I was capable of, but also to give a design of one in the manner I would chuse to erect it, upon the annexed copper-plate.

Plan of the Green house.

- A. The Ground plan of the Green-house.
- B.B. The Ground Plan of the two Stoves.
- C.C.C. The Sheds behind the Green-house and Stoves.
- D.D. The passage of communication between the Green-house and Stoves, where the Stairs are placed which lead to the Rooms over the Green-house.
- E.E. The Section of the Flues in the back of the Stoves.
- F. The upright of the Green-house and Stoves.

J. Haynes Sculp.

As to the length of these houses, that must be proportioned to the number of plants they are to contain, or the fancy of the owner; but their depth should never be greater than their height in the clear, which in small, or middling houses, may be sixteen or eighteen feet, but for large ones, from twenty to twenty-four feet, is a good proportion; for if the Green-house is long, and too narrow, it will have a bad appearance both within and without, nor will it contain so many plants, if proper room be allowed for passing in front, and on the backside of the stands on which the plants are placed; and on the other hand, if the depth of the Green-house is more than twenty-four feet, there must be more rows of plants placed to fill the house, than can with conveniency be reached in watering and cleaning; nor are houses of too great depth so proper for keeping of plants, as those of moderate size.

The windows in front should extend from about one foot and a half above the pavement, to within the same distance of the ceiling, which will admit of a cornice round the building, over the heads of the windows. As it is necessary to have these windows so long, it will be impossible to make them in proportion as to their breadth; for if in the largest buildings the sashes are more than seven, or seven feet and a half broad, they will be so heavy and troublesome to move up and down, as to render it very difficult for one person to perform; besides, their weight will occasion their soon decaying. There is also another inconvenience in having the windows too broad, which is that of fixing proper shutters to them, in such a manner as that they may fall back close to the piers, so as not to be incommodious, or when open to obstruct any part of the rays of light from reaching the plants. The piers between these windows should be as narrow as possible to support the building, for which reason I should chuse to have them of stone, or of hard well-burnt bricks; for if they are built with fine rubbed bricks, those are generally so soft, that the piers will require to be made thicker, and the building will be less strong, especially if there are any rooms over the Green-house; which is what I would always advise, as being of great use to keep the frost out in very hard winters. If these piers are made of stone, I would advise them to be two feet and a half in diameter, worked as columns cylindrical, whereby the rays of the sun will not be taken off, or obstructed by the corners of the piers, which it would be if they were square; but if they are built with bricks, it will be proper to make them three feet in front, otherwise they will be too weak to support the building; these I would also advise to be sloped off toward the inside to admit the sun.

At the back of the Green-house there may be erected a house for tools, and for many other purposes, which will be extremely useful, and will also prevent the frost from entering the house on the backside, so that the wall between these need not be more than two bricks and a half in thickness; whereas were it quite exposed behind, it should be at least three bricks, or three and a half in thickness; and by this contrivance, if you are willing to make a handsome building, and to have a noble room over the Green-house, you may make the room over the tool-house, and carry up the staircase in the back, so as not to be seen in the Green-house, and hereby you may have a room twenty-five or thirty feet in width, and of a proportionable length; and under this stair-case there should be a private door into the green-house, at which the gardener may enter in hard frosty weather, when it will not be safe to open any of the glasses in the front. The floor of the Green-house, which should be laid either with Bremen squares, Purbeck stone, or broad tiles, according to the fancy of the owner, must be raised two feet above the surface of the ground whereon the house is placed, which in dry ground will be sufficient; but if the situation is moist and springy, and thereby subject to damp, it should be raised at least three feet above the surface; and if the whole is arched with low brick

arches under the floor; it will be of great service in preventing the damp rising in winter, which are often very hurtful to the plants, especially in great thaws; when the air is often too cold to be admitted into the house, to take off the damp. Under the floor, about one foot from the front, I would advise a flue of one foot in width, and two feet deep, to be carried the whole length of the house, which may be returned against the back wall, and carried up in proper funnels adjoining to the tool-house, three times over each other, by which the smoke may pass off. The fireplace may be contrived at one end of the house, and the door at which the fuel is put in, as also the ash-grate, may be contrived to open into the tool-house, so that it may be quite hid from the sight, and be in the dry, and the fuel may be laid in the same shed, whereby it will always be ready for use.

I suppose many people will be surprised to see me direct the making of flues under a Green-house, which has been disused so long, and by most people thought of ill consequence; as indeed they have often proved, when under the direction of unskilful managers, who have thought it necessary, whenever the weather was cold to make fires therein; but however injurious flues may have been under such management; yet when skilfully looked after they will be found of very great service; for though perhaps it may happen, that there will be no necessity to make any fires in them for two or three years together, as when the winters prove mild there will not, yet in very hard winters they will be extremely useful to keep out the frost, which cannot be effected any other way, but with great trouble and difficulty.

Within side of the windows, in front of the Green-house, you should have good strong shutters, which should be made with hinges to fold back, that they may fall back quite close to the piers, that the rays of the sun may not be obstructed thereby. These shutters need not be above an inch and a half thick, or little more when wrought, which if made to join close, will be sufficient to keep out our common frost; and when the weather is so cold as to endanger the freezing in the house, it is but making a fire in the oven, which will effectually prevent it; and without this conveniency it will be very troublesome, as I have often seen, where persons have been obliged to nail mats before their windows, or to stuff the hollow space between the shutters, and the glass with straw, which when done, is commonly suffered to remain till the frost goes away; which if it should continue very long, the keeping the Green-house closely shut up, will prove very injurious to the plants; and as it frequently happens, that we have an hour or two of the sun-shine in the middle of the day, in continued frosts, which is of great service to plants, when they can enjoy the rays thereof through the glasses, so when there is nothing more to do than to open the shutters, which may be performed in a very short time, and as soon shut again when the sun is clouded, the plants may have the benefit thereof whenever it appears; whereas, where there is so much trouble to uncover, and as much to cover again, it would take up the whole time in uncovering and shutting them up, and thereby the advantage of the sun's influence would be lost. Besides, where there is so much trouble required to keep out the frost, it will be a great chance if it be not neglected by the gardener; for if he be not as fond of preserving his plants, and as much in love with them as his master, this labour will be thought too great by him; and if he takes the pains to cover the glasses up with mats, &c. he will not care to take them away again until the weather alters, so that the plants will be shut up close during the whole continuance of the frost.

There are some people who commonly make use of pots filled with charcoal to set in their Green-house in very severe frosts, but this is very dangerous to the persons who attend these fires, and I have sometimes known they have been almost suffocated therewith, and at the same time they are very injurious to the

G R E

plants; nor is the trouble of tending upon these small, and the many hazards to which the use of these fires is liable, have justly brought them into disuse with all skilful persons; and as the contrivances of flues, and of the fires, are but small charges in their first erecting, they are much to be preferred to any other method for warming the air of the house.

The wall on the back part of the house should be either laid over with stucco, or plastered with mortar, and white-washed, for otherwise the air in severe frost will penetrate through the walls, especially when the frost is attended with a strong wind, which is often the case in most severe winters. There are some persons who are at the expence of wainscoting their Green-houses, but when this is done, it is proper to plaster the walls with lime and hair behind the wainscot, to keep out the cold; and when they are lined with wainscot, they should be painted white, as should the cieling, and every part withinside of the house; for this reflects the rays of light in a much greater quantity than any other colour, and is of signal service to plants, especially in the winter, when the house is pretty much closed, and but a small share of light is admitted through the windows; for at such times I have observed, that in some Green-houses which have been painted black, or of a dark colour, the plants have cast most of their leaves.

Where green-houses are built in such places as will not admit of rooms over them, or the person is unwilling to be at the expence of such buildings, there must be care taken to keep out the frost from entering through the roof. To prevent which it will be very proper to have a thickness of Reeds, Heath, or Eurz, laid between the cieling and the tiles; in the doing of which there must be care taken in framing the joists, so as to support these, that their weight may not lie upon the ceiling, which might endanger it; for these should be laid a foot thick at least, and as smooth as possible, and fastened down well with laths to prevent their rising, and then covered over with a coat of lime and hair, which will keep out the air, and also prevent mice and other vermin from harbouring in them, which, if left uncovered, they would certainly do. For want of this precaution there are many Green-houses built, which will not keep out the frost in hard winters, and this is many times attributed to the glasses in front admitting the cold, when the fault is in the roof; for where there is only the covering, either of tiles or slates, over the cieling, every severe frost will penetrate through them.

In this Green-house you should have trussels, which may be moved out and into the house, upon which you should fix rows of planks, so as to place the pots or tubs of plants in regular rows one above another, whereby the heads of the plants may be so situated, as not to interfere with each other. The lowest row of plants, which should be the forwardest towards the windows, should be placed about four feet therefrom, that there may be a convenient breadth left next the glasses to walk in front; and the rows of plants should rise gradually from the first, in such a manner that the heads of the second row should be entirely advanced above the first, the stems only being hid thereby; and at the back side of the house there should be allowed a space of at least five feet, for the conveniency of watering the plants, as also to admit of a current of air round them, that the damps occasioned by the perspiration of the plants, may be the better dissipated, which, by being pent in too closely, often occasions a mouldiness upon the tender shoots and leaves, and when the house is close shut up, this stagnating rancid vapour is often very destructive to the plants; for which reason also you should never crowd them too close to each other, nor should you ever place Sedums, Euphorbiums, Torch Thistles, and other tender succulent plants, amongst Oranges, Myrtles, and other Evergreen trees; for, by an experiment which I made, anno 1729, I found that a Sedum placed in a Green-house among such trees, almost daily increased its weight, although there was no water given to it the

G R E

whole time; which increase of weight was owing to the moisture imbibed from the air, which, being replete with the rancid vapours perspired from the other plants, occasioned the leaves to grow pale, and in a short time they decayed and dropped off; which I have often observed has been the case with many other succulent plants, when placed in those houses which were filled with many sorts of Evergreen trees, that required to be frequently watered.

Therefore, to avoid the inconvenience which attends the placing of plants of very different natures in the same house, it will be very proper to have two wings added to the main Green-house, which, if placed in the manner expressed in the annexed plan, will greatly add to the beauty of the building, and also collect a greater share of heat. In this plan the Green-house is placed exactly fronting the south, and one of the wings faces the south-east, and the other the south-west; so that from the time of the sun's first appearance upon any part of the building, until it goes off at night, it is constantly reflected from one part to the other, and the cold winds are also kept off from the front of the main Green-house hereby; and in the area of this place you may contrive to place many of the most tender exotic plants, which will bear to be exposed in the summer season; and in the spring, before the weather will permit you to set out the plants, the beds and borders of this area may be full of Anemonies, Ranunculuses, early Tulips, &c. which will be past flowering, and the roots fit to take out of the ground by the time you carry out the plants, which will render this place very agreeable during the spring season, when the flowers are blown: and here you may walk and divert yourself in a fine day, when perhaps the air in most other parts of the garden will be too cold for persons not much used thereto, to take pleasure in being out of the house.

In the center of this area may be contrived a small basin for water, which will be very convenient for watering of plants, and add much to the beauty of the place; besides the water being thus situated, will be softened by the heat which will be reflected from the glasses upon it, whereby it will be rendered much better than raw cold water for these tender plants.

The two wings of the building should be contrived so as to maintain plants of differing degrees of hardiness, which must be effected by the situation and extent of the fire-place, and the manner of conducting the flues, a particular account of which will be exhibited under the article of STOVES. But I would here observe, that the wing facing the south-east should always be preferred for the warmest stove, its situation being such, as that the sun, upon its first appearance in the morning, shines directly upon the glasses, which is of great service in warming the air of the house, and adding life to the plants, after having been shut up during the long nights in the winter season. These wings being in the draught annexed, allowed sixty feet in length, may be divided in the middle by partitions of glass, with glass-doors to pass from one to the other. To each of these there should be a fire-place, with flues carried up against the back wall, through which the smoke should be made to pass, as many times the length of the house, as the height will admit of the number of flues; for the longer the smoke is in passing, the more heat will be given to the house, with a less quantity of fuel, which is an article worth consideration, especially where fuel is dear. By this contrivance you may keep such plants as require the same degree of heat in one part of the house, and those which will thrive in a much less warmth in the other part, but this will be more fully explained under the article of STOVES.

The other wing of the house, facing the south-west, may also be divided in the same manner, and flues carried through both parts, which may be used according to the seasons, or the particular sorts of plants which are placed therein, so that here will be four divisions in the wings, each of which may be kept up to

G R E

to a different degree of warmth, which, together with the Green-house, will be sufficient to maintain plants from all the several countries of the world; and without having these several degrees of warmth, it will be impossible to preserve the various kinds of plants from the several parts of Africa and America, which are annually introduced into the English gardens; for when plants from different countries are placed in the same house, some are destroyed for want of heat, while others are forced and spoiled by too much of it; and this is often the case in many places, where there are large collections of plants.

In the building these wings, if there are not sheds running behind them their whole length, the walls should not be less than three bricks thick; and if they are more, it will be better, because where the walls are thin, and exposed to the open air, the cold will penetrate them, and when the fires are made, the heat will come out through the walls, so that it will require a larger quantity of fuel, to maintain a proper temperature of warmth in the house. The back part of these houses having sloping roofs, which are covered either with tiles or slates, should also be lined with Reeds, &c. under the covering, as is before directed for the Green-house, which will keep out the cold air, and save a great expence of fuel; for the closer and better these houses are built, and the glasses of the slope, as also in front, well guarded by shutters, or Reeds in hard frost, the less fuel will be required to warm the houses; so that the first expence in building these houses properly, will be the cheapest, when the after-expence of fires is taken into consideration.

The sloping glasses of these houses should be made to slide and take off, so that they may be drawn down more or less in warm weather, to admit air to the plants; and the upright glasses in front may be so contrived, as that every other may open as doors upon hinges, and the alternate glasses may be divided into two; the upper part of each should be contrived so as to be drawn down like sashes, so that either of these may be used to admit air, in a greater or less proportion, according as there may be occasion.

But besides the Conservatories here mentioned, it will be proper to have a deep hot-bed frame, such as is commonly used to raise large annuals in the spring, into which may be set pots of such plants as come from Carolina, Virginia, &c. while the plants are too small to plant in the open air, as also many other sorts from Spain, &c. which require only to be screened from the violence of frosts, and should have as much free air as possible in mild weather; which can be no better effected than in one of these frames, where the glasses may be taken off every day when the weather will permit, and put on every night; and in hard frosts the glasses may be covered with mats, Straw, Peas-haulm, or the like, so as to prevent the frost from entering to the pots to freeze the roots of the plants, which is what will many times utterly destroy them, though a slight frost pinching the leaves or shoots, very seldom does them much harm; if these pits are sunk a foot or more, below the surface of the ground, they will be the better, provided the ground is dry, otherwise they must be wholly above ground; the sides of this frame should be built with brick, with a curb of wood laid round on the top of the wall, into which the gutters, on which the glasses slide may be laid; the back wall of this frame may be four feet high, and two bricks and a half thick, the front one foot and a half; the width of the inside of the frame about six feet, and the length in proportion to the number of plants to be contained therein.

GREWIA. Lin. Gen. Plant. 914. This genus of plants was constituted by Dr. Linnæus, who gave it this name in honour of Dr. Grew, F. R. S. who published a curious book of the anatomy of plants.

The CHARACTERS are,

The flower hath a thick leathery empalement, composed of five spear-shaped leaves, which are coloured, and spread open. The flower hath five petals of the same form, but smaller, and are indented at their base, where is situated

G R E

a scaly nectarium to each petal, which is thick and incurved, inclining to the border, to which the style is fixed; it hath many stamina, which are bristly, the length of the petals, terminated by roundish summits. In the center is situated the roundish germen, which is lengthened to a column, supporting a slender style, crowned by a four-cornered obtuse stigma. The germen afterward becomes a four-cornered berry with four cells, each inclosing one globular seed.

This genus of plants is ranged in the seventh section of Linnæus's twentieth class, which includes those plants whose flowers have many stamina joined to the style, forming a column of one body.

The SPECIES are,

1. **GREWIA** (*Occidentalis*) foliis subovatis crenatis. *Grewia with oval crenated leaves. Ulmi facie arbuscula Æthiopica, ramulis alatis, floribus purpurascens.* Hort. Amst. 1. p. 165. tab. 85. *Ethiopian Shrub with the appearance of Elm, winged branches, and purplish flowers.*
2. **GREWIA** (*Africanus*) foliis ovato-lanceolatis serratis. *Grewia with oval spear-shaped leaves which are sawed.*

The first sort has been long preserved in many curious gardens, both in England and Holland, and is figured by Dr. Plukenet, by the title of *Ulmifolia arbor Africana baccifera, floribus purpureis*; but by Dr. Boerhaave it was supposed to be one of Father Plumier's American plants, intitled *Guidonia Ulmi foliis, flore roseo*; but the characters of this do not at all agree with those of the *Guidonia*, that particular species of this genus being in the royal garden at Paris, which is extremely different from this. It grows naturally at the Cape of Good Hope, from whence I have received the seeds, which have succeeded in the Chelsea garden.

This will grow to the height of ten or twelve feet, and has a stem and branches very like those of the small-leaved Elm, the bark being smooth, and of the same colour as that of Elm when young; the leaves are also very like those of the Elm, and fall off in winter; the flowers are produced singly along the young branches from the wings of the leaves, which are of a bright purple colour; these appear toward the end of July, and continue in August, and the beginning of September, but are never succeeded by fruit in this country.

This may be propagated from cuttings or layers; the cuttings should be taken off, and planted in April, before the buds swell, for they do not succeed well after; these cuttings should be planted in small pots filled with loamy earth, and the pots should be plunged into a moderate hot-bed of tanners bark, where, if they are duly watered, and in the heat of the day shaded from the sun, they will take good root in about two months, and may then be gradually inured to bear the open air, into which they should be removed in June, and placed in a sheltered situation, where they may remain till autumn, when they must be removed into the green-house; the best time to lay down the layers of this plant is in the spring, before the buds come out, and these will be rooted by the same time the following year, when they may be cut off from the old plants, and planted each into a separate pot filled with a soft loamy soil.

The best time to remove or transplant this plant is, either in the spring, just before the buds begin to swell, or in autumn, when the leaves begin to drop; for in summer, when the plants are in full leaf, it will be very improper to disturb them.

In winter these plants should be placed in the green-house, for they are too tender to live abroad in England; but they should have as much free air as possible in mild weather, for they only require to be protected from frost, and after their leaves are fallen, they will require very moderate watering; but in summer they should be constantly watered three or four times a week in dry weather, and placed in a sheltered situation, with other hardy green-house plants, where they will add to the variety.

The seeds of the second sort were sent me by Mons. Richard, gardener to the King of France at Marseilles,

feilles, which were brought from Senegal in Africa, by Mons. Adanson; this rises in this country with a shrubby stalk five or six feet high, sending out many lateral branches, which are covered with a brown hairy bark, and garnished with oval spear-shaped leaves, about two inches long, and one inch and a quarter broad in the middle, having several transverse veins from the midrib to the sides, where they are sawed; these are placed alternately on the branches, having very short foot-stalks, and continue in verdure through the year; the plants are young, so have not as yet flowered in England, therefore I can give no further account of them.

This sort is tender, so will not live through the winter in England, unless it is placed in a warm stove; nor do those plants thrive well, which are placed on shelves in the dry stove; therefore the only method to have them succeed, is to place them in the bark-bed in the tan-stove, where the plants have grown very well for some years. In summer these plants require a good share of free air to be admitted to them, and should have water three or four times a week in warm weather; but in winter they must be sparingly watered, and require to be kept warm.

G R I A S. Lin. Gen. 659. Anchovy Pear.

The CHARACTERS are,

The empalement is cup-shaped, of one leaf, cut into four equal segments; the flower has four leathery concave petals, and many bristly stamina which are inserted to the receptacle, terminated by roundish summits, and a depressed germen immersed in the empalement, having no style, crowned by a four-cornered cross-shaped stigma, which afterward becomes a fleshy berry, with a large nut having eight furrows, and one cell containing a large pointed seed.

This genus of plants is ranged in the first order of Linnæus's thirteenth class, intitled Polyandria Monogynia, the flower having many stamina and one style.

We know but one SPECIES of this genus, viz.

1. GRIAS (*Cauliflora*). Lin. Sp. 732. *Anchovy Pear*. *Palmis affinis malus Persica maxima, caudice non ramosa, foliis longissimis, flore tetrapetalo pallide luteo, fructu ex arboris trunco prodeunte.* Sloan. Hist. Jam. 2. p. 122.

This plant grows naturally in Jamaica, and in many other warm parts of America, where it rises with a strait undivided stem about twenty feet high, having a gray bark, marked with the vestigia of the fallen leaves; the top of the stem is garnished with leaves near two feet long and six inches broad, sitting close without foot-stalks; these have one longitudinal midrib with several transverse veins, and are of a lucid green; the flowers come out from the stem below the leaves, having no foot-stalk, in some places one, and in others they are in clusters, each having four thick yellow petals, and a great number of stamina which are fixed to the empalement of the flower; the germen is included in the empalement, which afterward becomes a large oval Plumb, including a large pointed nut.

The fruit of this tree is by the Spaniards in the West-Indies pickled and sent to old Spain as presents, who eat them as Mango's, and some say the ripe fruit is eaten as a desert.

The plant is propagated by planting of the stones, which should be put into the ground soon after the fruit is gathered, and the plants must be constantly kept in the bark-bed in the stove, otherwise it will not thrive in this country.

G R O N O V I A. Martyn. Cent. 4. Lin. Gen. Plant. 284. The name of this genus was given by the late Dr. Houston, in honour of Dr. Gronovius, a learned botanist at Leyden.

The CHARACTERS are,

The flower hath a permanent empalement of one leaf, which is coloured, and cut to the middle into five segments. It hath five small petals which are fixed to the cuts of the empalement, and five hairy stamina the length of the petals, which are inserted into the empalement, and are placed alternate with the petals, terminated by twin summits which are erect. The germen is situated under the flower, sup-

porting a slender style which is longer than the stamina, crowned by an obtuse stigma. The germen afterward becomes a roundish-coloured fruit with one cell, inclosing one large roundish seed.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which includes those plants whose flowers have five stamina and one style.

We know but one SPECIES of this genus, viz.

G R O N O V I A (*Scandens*). Hort. Cliff. 74. *Gronovia scandens lappacea, pampinea fronde.* Houst. *Climbing burry Gronovia.*

This plant was discovered by the late Dr. Houstoun at La Vera Cruz, from whence he sent the seeds to Europe, which have succeeded in many gardens. It is an annual plant, which sends forth many trailing branches like those of the Cucumber, which are closely set with broad green leaves, in shape like those of the Vine; but they are covered with small spines on both sides, which sting like the Nettle: the branches have many tendrils or clasps, by which they fasten themselves to whatever plants they grow near, and will rise to the height of six or eight feet; the flowers are small, and of a greenish yellow colour, so make no great appearance.

This being a very tender plant, must be raised on a hot-bed early in the spring, and afterward placed in the bark-stove, and treated in the same way as the Momordica, with which management it will produce ripe seeds; but this having neither use or beauty, is rarely cultivated but in botanic gardens for the sake of variety.

G R O S S U L A R I A. Raii Meth. Plant. 145. Tourn. Inst. R. H. 639. tab. 409. Ribes. Lin. Gen. Plant. 247. Gooseberry; in French, *Groselier*.

This and the Currant are by Tournefort placed in the same genus, under the title of Grossularia; they are also joined together by Dr. Linnæus, under the title of Ribes, for in their principal characters they agree; so according to the systems of botany, they should be included in the same genus; but this may not be quite so proper in a body of gardening, for as these fruits have always passed under different denominations, so if they are here joined together, it may occasion some confusion among those who do not enter into the study of botany. Mr. Ray has separated these into different genera, and makes the difference of Gooseberry from the Currant, to consist in the first having thorns on the branches, and the fruit growing single; whereas the latter hath smooth branches, and the fruit growing in long bunches; and although these differences may not be strictly scientific, yet it may be allowed sufficient to distinguish them among gardeners.

The CHARACTERS are,

The flower has a permanent empalement of one leaf, cut into five segments at the top, which is swollen, concave, and coloured. It hath five small, obtuse, erect petals, which rise from the border of the empalement; and five awl-shaped stamina, which are inserted into the empalement, terminated by compressed prostrate summits. The germen is situated below the flower, having a bifid style crowned by an obtuse stigma, and afterward becomes a globular berry having a navel, with one cell, which is filled with roundish compressed seeds included in a pulp.

This genus of plants is ranged by Dr. Linnæus in the first section of his fifth class, intitled Pentandria Monogynia, which contains those plants whose flowers have five stamina and one style.

The SPECIES are,

1. GROSSULARIA (*Reclinatum*) ramis reclinatis aculeatis, pedunculis triphyllis. *Gooseberry with reclining branches armed with spines, and a three-leaved foot-stalk.* Grossularia spinosa, fructu obscure purpurascens. J. B. 1. 48. *Prickly Gooseberry with a dark purplish fruit.*
2. GROSSULARIA (*Hirsuta*) ramis aculeatis, baccis hirsutis. *Gooseberry with prickly branches and hairy berries.* Grossularia fructu maximo hispido margaritarum ferè colore. Raii Hist. 1484. *Gooseberry with a very large rough fruit, almost of a pearl colour.*

3. GROS-

3. GROSSULARIA (*Uva Crispa*) ramis aculeatis, erectis, baccis glabris. *Gooseberry with erect prickly branches, and smooth berries.* Grossularia simpliciacino, vel spinosa sylvestris. C. B. P. 455. *Gooseberry with a single fruit, or wild prickly Gooseberry.*
4. GROSSULARIA (*Oxyacanthoides*) ramis undique aculeatis. *Gooseberry whose branches are armed on all sides with spines.* Grossularia oxyacanthæ foliis amplioribus è sinu Hudsonis. Pluk. Amalth. 212. *Gooseberry with larger Hawthorn leaves from Hudson's Bay.*
5. GROSSULARIA (*Cynosbati*) aculeis subaxillaribus, baccis aculeatis racemosis. *Gooseberry with spines on the lower part of the branches, and prickly berries growing in clusters.* Ribes aculeis subaxillaribus, baccis aculeatis racemosis. Lin. Sp. Plant. 202. *Current with spines on the lower part of the branches, and prickly berries growing in bunches.*

The sorts which are here enumerated, are supposed to be distinct species; but there are several other varieties which have been obtained from seeds, and are propagated for sale in the nurseries; most of these are titled from the persons who raised them, as Lamb's Gooseberry, Hunt's Gooseberry, Edwards's Gooseberry, &c. and as there are frequently new varieties obtained, it is needless to enumerate them here, therefore I shall proceed to their culture.

These are propagated either by suckers taken from the old plants, or by cuttings; the latter of which I prefer to the former, because those plants which are produced from suckers are always more disposed to shoot out a greater number of suckers from their roots, than such as are raised from cuttings, which generally form much better roots.

The best season for planting these cuttings is in autumn, just before their leaves begin to fall; observing always to take the handiomest shoots, and from such branches as generally produce the greatest quantity of fruit; for if you take those which are produced from the stem of the old plants (which are commonly very luxuriant) they will not be near so fruitful as those taken from bearing branches: these cuttings should be about six or eight inches long, and must be planted in a border of light earth, exposed to the morning sun, about three inches deep, observing to water them gently when the weather proves dry, to facilitate their taking root; and in the summer, when they have put out branches, you should rub off all the under shoots, leaving only the uppermost or strongest, which should be trained upright, to form a regular stem. In October following these plants may be removed; at which time you should prepare an open spot of fresh earth, which should be well dug, and cleansed from all noxious weeds, roots, &c. and being levelled, you should proceed to take up your plants, trimming their roots, and cutting off all lateral side branches; then plant them at three feet distance row from row, and one foot asunder in the rows, observing to place some short sticks to the plants, in order to train their stems upright and regular. In this place they may remain one or two years, being careful to keep them clear from weeds, as also to trim off all lateral shoots which are produced below the head of the plant, so that the stem may be clear about a foot in height above the surface of the earth, which will be full enough; and as the branches are produced commonly very irregular in the head, you must cut out such of them as cross each other, or thin them where they are too close, whereby the head of the plant will be open, and capable of admitting the air freely into the middle, which is of great use to all kinds of fruits.

After these plants have remained in this nursery one or two years at most, they will be fit to transplant to the places where they are designed to remain; for it is not so well to let them grow in the nurseries too large which will occasion their roots to be woody, whereby the removing of them will not only hazard the growth of the plants, but such of them as may take very well will remain stined for two or three years, before they will be able to recover their check. The soil in which these plants thrive to the greatest advantage, is a rich light

earth; though they will do very well upon middling soils, which are not too strong or moist, and in all situations; but where the fruit is cultivated, in order to procure it in the greatest perfection, they should never be planted in the shade of other trees, but must have a free open exposure. The distance they ought to be planted is eight feet row from row, and six feet asunder in the rows. The best season for transplanting them is in October, when their leaves begin to decay; observing, as was before directed, to prune their roots, and trim off all lateral shoots, or such as cross each other, shortening all long branches, so as to make the head regular.

In the pruning of these shrubs most people make use of garden-shears, observing only to cut the head round, as is practised for Evergreens, &c. whereby the branches become so much crowded, that what fruit is produced, never grows to half the size as it would do were the branches thinned, and pruned according to art; which should always be done with a pruning-knife, shortening the strong shoots to about ten inches, and cutting out all those which grow irregular, thinning the fruit-bearing branches where they are too thick, observing always to cut behind a leaf bud. With this management your fruit will be near twice as large as those which are produced upon such bushes as are not thus pruned, and the shrubs will continue in vigour much longer; but you must observe to keep the ground clear from weeds, and dig it at least once a year; and every other year you should bestow a little rotten dung upon it, which will greatly improve the fruit.

It is a common practice with the gardeners near London, who have great quantities of these bushes in order to supply the markets, to prune them soon after Michaelmas, and then to dig up the ground between the rows, and plant it with Coleworts for spring use, whereby their ground is employed all the winter, without prejudicing the Gooseberries; and in hard winters these Coleworts often escape, when those which are planted in an open exposure are all destroyed; and these are generally pulled up for use in February or March, so that the ground is clear before the Gooseberries come out in the spring; which is a piece of husbandry well worth practising where ground is dear, or where persons are confined for room.

GROVES are the greatest ornaments to a garden, nor can a garden be complete which has not one or more of these. In small gardens there is scarce room to admit of Groves of any extent, yet in these there should be at least one contrived, which should be as large as the ground will allow it; and where these are small, there is more skill required in the disposition, to give them the appearance of being larger than they really are.

Groves have been in all ages held in great veneration: the ancient Romans had a sort of Groves near several of their temples, which were consecrated to some God, and were called luci by antiphrasis, à non lucendo, as being shady and dark; and these were dedicated to holy uses, being places of solitude and retirement, and were never to be violated with the ax.

These Groves are not only great ornaments to gardens, but are also the greatest relief against the violent heats of the sun, affording shade to walk under in the hottest part of the day, when the other parts of the garden are useless; so that every garden is defective which has not shade.

Groves are of two sorts, viz. open and close Groves: open Groves are such as have large shady trees, which stand at such distances, as that their branches may approach so near each other, as to prevent the rays of the sun from penetrating through them; but as such trees are a long time in growing to a proper size for affording a shade, so where new Groves are planted, the trees must be placed closer together, in order to have shade as soon as possible; but in planting of these Groves, it is much the best way to dispose all the trees irregularly, which will give them a greater magnificence, and also form a shade sooner, than when the

trees are planted in lines; for when the sun shines between the rows of trees, as it must do some part of the day in summer, the walks between them will be exposed to the heat at such times, until the branches of these trees meet; whereas in the irregular plantations, the trees intervene, and obstruct the direct rays of the sun.

When a person who is to lay out a garden, is so happy as to meet with large full grown trees upon the spot, they should remain inviolate, if possible; for it will be better to put up with many inconveniencies, than to destroy these, which will require an age to retrieve; so that nothing but that of offending the habitation, by being so near as to occasion great damps or obstructing fine views, should tempt the cutting of them down.

Most of the Groves which have been planted either in England, or in those celebrated gardens of France, are only a few regular lines of trees; many of which are avenues to the habitation, or lead to some building, or object; but these do not appear so grand, as those which have been made in woods where the trees have grown accidentally, and at irregular distances; and where the trees have large spreading heads, and are left at such a distance, as to permit the Grass to grow under them, then they afford the greatest pleasure: for nothing is more noble than fine spreading trees with large stems, growing through Grass, especially if the Grass is well kept, and has a good verdure; besides, most of these planted Groves have generally a gravel-walk, made in a strait line between them, which greatly offends the sight of persons who have true taste; therefore whenever a gravel-walk is absolutely necessary to be carried through these Groves, it will be much better to twist it about, according as the trees naturally stand, than to attempt regularity; but dry walks under large trees are not so useful as in open places, because the dropping of the trees will render these walks useless after rain, for a considerable time.

Close Groves have frequently large trees standing in them, but the ground is filled under these with shrubs, or under-wood; so that the walks which are made in them are private, and screened from winds, whereby they are rendered agreeable for walking, at such times when the air is too violent or cold for walking in the more exposed parts of the garden.

These are often contrived so as to bound the open Groves, and frequently to hide the walls, or other inclosures of the garden; and when they are properly laid out, with dry walks winding through them, and on the sides of these sweet-smelling shrubs and flowers irregularly planted, they have a charming effect; for here a person may walk in private, sheltered from the inclemency of cold or violent winds, and enjoy the greater sweets of the vegetable kingdom: therefore where it can be admitted, if they are continued round the whole inclosure of the garden, there will be a much greater extent of walk; and these shrubs will appear the best boundary, when there are not fine prospects to be gained.

These close Groves are by the French termed *bosquets*, from the Italian word *boschetto*, which signifies a little wood, and in most of the French gardens there are many of them planted; but these are reduced to regular figures, as ovals, triangles, squares, and stars; which have neither the beauty or use which those have that are made irregularly, and whose walks are not shut up on each side by hedges, which prevents the eye from seeing the quarters; and these want the fragrantcy of the shrubs and flowers, which are the great delight of these private walks: add to this, the keeping of the hedges in good order is attended with a great expence, which is a capital thing to be considered in the making of gardens.

GUAIABARA. See COCCOLOROS.

GUAJACANA. See DIOSPYROS.

GUAJACUM. Plum. Nov. Gen. 39. tab. 17. Lin. Gen. Plant. 465. *Lignum Vitæ*, or Pockwood.

The CHARACTERS are,

The flower hath a concave empalement of one leaf, which is quinquesfid. It hath five oblong, oval, concave petals, which are inserted in the empalement and spread open, and ten erect stamina inserted in the empalement, terminated by small summits. The style is long and slender, the germen is oval and pointed, and the stigma is single and slender. The germen afterward becomes a berry which is roundish, with an oblique point, and deeply furrowed, inclosing an oval hard seed.

This genus of plants is ranged in the first section of Linnæus's tenth class, intitled Decandria Monogynia, which includes those plants whose flowers have ten stamina and one style.

The SPECIES are,

1. GUAJACUM (*Officinale*) foliolis bijugatis obtusis. Lin. Sp. Plant. 381. *Guajacum with obtuse lobes placed by pairs. Guajacum flore cæruleo, fructu subrotundo. Plum. Nov. Gen. 391. Guajacum with a blue flower and a roundish fruit.*
2. GUAJACUM (*Sanctum*) foliolis multijugatis obtusis. Lin. Sp. Plant. 382. *Guajacum with many pair of obtuse lobes. Guajacum flore cæruleo fimbriato, fructu retragono. Plum. Nov. Gen. 391. Guajacum with a blue fringed flower, and a four-cornered fruit.*
3. GUAJACUM (*Afrum*) foliolis multijugatis obtusis. Lin. Sp. Plant. 382. *Guajacum with many pair of acute-pointed lobes. Guilandinoides. Hort. Cliff. 489. and the Afra arbor acaciæ similis, foliis myrti aculeatis splendentibus. Boerh. Ind. alt. 2. p. 57. African-tree like the Acacia, with shining, acute-pointed, Myrtle leaves.* The first sort is the common *Lignum Vitæ*, or *Guajacum*, which is used in medicine, and grows naturally in most of the islands in the West-Indies, where it rises to be a very large tree, having a hard, brittle, brownish bark, not very thick; the wood is firm, solid, and ponderous, appearing very resinous, of a blackish yellow colour within, and of a hot aromatic taste; the smaller branches have an Ash-coloured bark, garnished with leaves, which are divided by pairs, each pair having two pair of small, oval, blunt leaves (or pinnæ) of a stiff consistence, and a lucid green; the flowers are produced in clusters at the end of the branches, composed of five oval concave petals, of a fine blue colour; in the center of these is fixed a style with an oval germen, crowned by a slender stigma; and round this is situated from ten to twenty stamina, which are as long as the style, terminated by sickle-shaped summits. Dr. Linnæus supposes the flowers to have but ten stamina, whereas they certainly have near twenty.

The bark and wood of this tree are much of the same nature, only the wood is accounted hotter; they are used in diet-drinks to purify and cleanse the blood, and to cause sweating; they are esteemed good for the gout and dropsy, the king's-evil, and particularly for the French pox. The gum or resin, which is black, shining, and brittle, and when powdered, of a greenish white colour, of an aromatic smell, and poignant taste, is somewhat cathartic, and a good purge in rheumatic cases, to the quantity of two scruples mixed with the yolk of an egg, and given in a convenient vehicle.

The wood of this tree is so hard as to break the tools in felling them, so they are seldom cut down for fire-wood, being difficult to burn; but the wood is of great use to the sugar-planters, for making of wheels and cogs for the sugar-mills, &c. It is also frequently brought to Europe, and wrought into bowls, and other utensils are made of the wood.

This tree can only be propagated by seeds, which must be procured from the countries where it naturally grows; these must be fresh, otherwise they will not grow; when they arrive, they should be sown in pots filled with light earth, and plunged into a good hot-bed: if the seeds are good, and the bed in which they are plunged is of a proper temperature of heat, the plants will appear in six weeks or two months after, and in six weeks will grow to be of strength enough more for

for transplanting; then they should be carefully taken out of the seed-pots, so as to preserve their roots as entire as possible, and each planted in separate small pots filled with light earth, and plunged into a new hot-bed of tanners bark, where they must be shaded from the sun till they have taken fresh root; then they must be treated in the same manner as other tender exotic plants from warm countries, admitting a large share of free air to them when the weather is warm: they will require to be frequently refreshed with water in warm weather, but it must be given them with caution, for too much wet will infallibly destroy them. While the plants are young, they may be kept during the summer season in a hot-bed of tanners bark under a frame; but in the autumn they must be removed into the bark-stove, and plunged into the hot-bed of tan, where they should constantly remain, and must be treated in the same manner as other tender plants, being careful not to give them too much water in the winter, when it is very prejudicial to them, and in summer they should have a large share of free air admitted to them every day. With this treatment the plants will thrive very well, but they are plants of slow growth in their own country, so cannot be expected to make great progress in Europe.

The second sort has many small leaves placed along the midrib by pairs, which are rounded and obtuse at their ends, but narrow at their base: they are of the same consistence with those of the former sort, but of a darker green colour; the flowers are produced in loose bunches toward the end of the branches, which are of a fine blue colour, and their petals are fringed on their edges. This is called in some of the islands Bastard Lignum Vitæ; I received it from Antigua by that title. It requires the same treatment as the first sort, and is propagated by seeds in the same way.

I have also received specimens from the island of Barbuda of one, which seems different from either of those before-mentioned: the branches have the same appearance with those of the first sort, but the leaves are larger and indented at their extremities, and are placed all round the branches, on very short foot-stalks; the flowers were broken off, so I cannot determine the difference between them, but by all appearance they seem to be of the same genus.

The third sort has been long an inhabitant in some of the curious gardens in England and Holland, but seldom produces flowers in Europe. This grows naturally at the Cape of Good Hope, from whence the seeds were brought first to Holland, where it passed for a species of Acacia, until it produced its flowers; which, by the account given of them by the late Dr. Boerhaave, were of the butterfly kind; but whether Dr. Linnæus has seen the flowers or not, I cannot say; however, he has removed it from that class of plants, and has added it to this genus; and as I have not yet seen the flowers, so I do not know if it is rightly placed. The plants retain their leaves all the year, and will live in a good green-house in winter, but in summer must be placed abroad with other green-house plants. It is of slow growth, and is with difficulty propagated by layers.

GUAJABA. See PSIDIUM.

GUAZUMA. See THEOBROMA.

GUIDONIA. See SAMYDA.

GUILANDINA. Lin. Gen. Plant. 464. Bonduc. Plum. Nov. Gen. 25. tab. 39. The Nickar-tree.

The CHARACTERS are,

The empalement of the flower is of one leaf, is bell-shaped, and cut at the top into five equal segments: the flower has five concave spear-shaped petals which are equal, and sit close to the empalement, into which they are inserted. It hath ten awl-shaped stamina which are erect, and inserted in the empalement, being alternately shorter than each other, and terminated by obtuse summits. In the center is situated an oblong germen, supporting a slender style the length of the stamina, crowned by a single stigma. The germen afterward becomes a rhomboid pod, with

a convex suture on the upper side; it is swelling and compressed, having one cell, including oval hard seeds, which are separated by partitions.

This genus of plants is ranged in the first section of Linnæus's tenth class, in which he includes the plants whose flowers have ten stamina and one style.

The SPECIES are,

1. *GUILANDINA (Bonduc) aculeata pinnis ovatis foliolis aculeis solitariis.* Lin. Sp. 545. *Prickly Guilandina with oval-winged leaves, whose small leaves are armed with single spines.* Bonduc vulgare majus polyphyllum. Plum. Nov. Gen. 25. *Common greater Bonduc, having many leaves, called yellow Nickar.*
2. *GUILANDINA (Bonducella) aculeata, pinnis oblongo-ovatis foliolis aculeis geminis.* Lin. Sp. 545. *Prickly Guilandina with oblong oval leaves, having spines by pairs.* Bonduc vulgare minus polyphyllum. Plum. Nov. Gen. 25. *Smaller common Bonduc, or Nickar-tree having many leaves, called gray Nickar.*
3. *GUILANDINA (Glabra) inermis foliis bipinnatis, foliolis ovatis acutis alternis.* *Smooth Guilandina with double winged leaves, whose small leaves are oval-pointed and alternate.*
4. *GUILANDINA (Moringa) inermis, foliis subpinnatis, foliolis inferioribus ternatis.* Flor. Zeyl. 155. *Smooth Guilandina with winged leaves, whose under small leaves are trifoliate.* Moringa Zeylanica, foliorum pinnis pinnatis, flore majore, fructu anguloso. Burm. Zeyl. 162. tab. 75. *Morunga of Ceylon, with double-winged leaves, a larger flower, and an angular fruit.*
5. *GUILANDINA (Dioica) inermis foliis bipinnatis basi apiceque simpliciter pinnatis.* Lin. Sp. 546. *Guilandina with smooth branches, doubly winged leaves, whose base and tops are single winged.* Bonduc Canadense polyphyllum, non spinosum, mas & foemina. Du Hamel. *Canada Nickar-tree having many leaves, which have no spines, and are male and female in different plants.*

The first and second sorts grow naturally in most of the islands in the West-Indies, where they twine their stalks about any neighbouring support, and rise to the height of twelve or fourteen feet. The leaves of the first sort are near a foot and a half long, and are composed of six or seven pair of pinnæ, or wings, each of which has as many pair of lobes, or small leaves set along the midrib; these are oval and entire; the foot-stalk or principal midrib of the leaf, is armed with short, crooked, single thorns, which are placed irregularly; the stalks are closely armed with the like thorns, which are larger. The stalks at first grow erect, but afterward they twine about the neighbouring trees or shrubs, being too weak to stand without support: the flowers come out in long spikes from the wings of the stalk; they are composed of five concave yellow petals, which are equal; in the center is situated the oblong germen, surrounded by ten stamina. After the flower is past, the germen becomes a broad thick pod, about three inches long and two broad, closely armed with slender spines, opening with two valves, each inclosing two hard seeds about the size of children's marbles, of a yellowish colour.

The second sort differs from the first, in having much smaller leaves, which are set close together; and below each pair of lobes are situated two short stiff crooked spines, which are placed opposite; the flowers are of a deeper yellow colour than those of the first sort, and the seeds are of an Ash-colour.

The third sort was discovered by the late Dr. Houston at Campeachy, from whence he sent the dried samples to England, but there was no fruit on the trees at the time when he was there; but he mentions that this sort had an upright stem, which was of a large size, dividing into many branches; these are garnished with double winged leaves, which are smooth; the wings come out alternate, each leaf being composed of four pair, but the lobes are placed opposite upon the middle rib; they are oval, but end in a point, and are of a light green colour.

The fourth sort grows naturally in the island of Ceylon, and in several places on the Malabar coast, from

from whence the seeds were brought to England. This in its native country rises to the height of twenty-five or thirty feet, with a strong stem, covered with a smooth bark, which in the young branches is green, but on the older it is of an Ash-colour; the root grows knobbed, and very thick. This, when young, is scraped and used by the inhabitants as Horse-radish is in Europe, having much the same sharp taste; the branches are garnished with decomposed winged leaves; those which are situated at the base have but three leaves, but above, the leaves are branched out into several divisions, which are again divided into smaller, having each five or six pair of oval lobes, terminated by an odd one; they are of a light green, and a little hoary on their under side. The flowers are produced in loose bunches from the side of the branches; they are composed of an unequal number of petals, from five to ten; they have ten short stamina surrounding the germen, which afterward turns to a long taper pod, including several angular seeds, covered with a thin membrane. These have a flavour like the root. These four sorts are natives of warm countries, so will not live through the winter in England, unless they are placed in a warm stove, and the pots plunged into the tan-bed. They are propagated by seeds, but those of the two first sorts are so hard, that unless they are soaked two or three days in water before they are put into the ground, or placed under the pots in the tan-bed to soften their covers, they will remain years in the ground without vegetating: when the plants come up, they will be fit to transplant in a short time; then they should be each transplanted into a small pot filled with light fresh earth, and plunged into a moderate hot-bed of tanners bark, shading them till they have taken fresh root; then they must be treated in the same manner as other tender exotic plants, giving them a large share of air in warm weather, and but little water; and when the plants have advanced to be too tall to remain in the frames, they must be removed into the bark-stove and plunged into the hot-bed, where they will make great progress, provided they have not too much water, especially during the winter season, for these plants are very impatient of moisture in cold weather.

The fourth sort requires the same treatment as those before-mentioned, but the seeds will grow without being steeped in water; and the plants are with difficulty shifted from one pot to another, for their roots are large, fleshy, and have but few fibres; so that unless great care is taken, all the earth will fall away from them, which often causes their stalks to decay almost to the root, and sometimes occasions the loss of the plants. This plant must be sparingly watered at all times, but particularly in cold weather, when moisture will cause them to rot in a short time.

The fifth sort grows naturally in Canada, from whence the plants were brought to Paris, where it has been some years cultivated; but about fourteen years past, it was first brought to England. This, in the country where it naturally grows, rises with an erect stem to the height of thirty feet or more, dividing into many branches, which are covered with a bluish Ash-coloured bark very smooth, and garnished with large decomposed winged leaves which are of the oval shape, very smooth and entire, but are ranged alternate on the midrib; these fall off in the autumn, and new ones come out late in the spring.

There are male and female of this sort in different plants; as these have not as yet flowered in any of the English gardens, so I can give no farther account of them nor of the fruit, having never seen any of them. This sort lives abroad in the open air, and is never hurt by frost. It is propagated by cutting off some of the horizontal roots, which will cause them to shoot upward, so it may be taken from the old root, and planted in pots, whereby the plant may be multiplied, or by suckers from the root. It requires a light soil, not too moist.

GUNDELIA. Tourn. Cor. 51. tab. 586. Lin. Gen. Plant. 828. Hacub. Vaill. Ac. Reg. Scien. 1718.

This plant was so named by Dr. Tournefort, in honour of Dr. Gundelscheimer, who found it in his travels in company with Dr. Tournefort in the Levant.

The CHARACTERS are,

It hath an uniform tubulous flower, composed of many hermaphrodite florets, which are incircled by leaves. They have but one petal which is closed at the bottom, but swells at the top, where it is slightly cut into five segments: they have five short hairy stamina, terminated by long cylindrical summits. The oval germen is situated at the bottom of the flower, crowned by small scales, supporting a slender style which is longer than the petal, terminated by two revolving stigmas. The germen afterward becomes a roundish single seed inclosed in the common receptacle, which is conical, and the seeds are separated by a chaffy down.

This genus of plants is by Tournefort referred to his twelfth class, which contains the herbs with flosculous flowers. Dr. Linnæus ranges it in the fifth section of his nineteenth class, intitled Syngenesia Polygamia segregata, which includes those plants whose flowers have a common empalement, and each of the florets are included in another.

We have but one distinct SPECIES of this genus at present in England, viz.

GUNDELIA. Lin. Sp. Plant. 814. There is no English title to this plant, but there are two varieties of it mentioned by Tournefort, which are supposed to arise from the same seeds, as they were found growing promiscuously together. These are,

1. GUNDELIA (*Tournefortii*) Orientalis acanthi aculeati foliis, floribus intense purpureis, capite araneosâ lanugine obsito. Tourn. Cor. 51. *Eastern Gundelia with prickly Bear's-breech leaves, deep purple flowers, and a head covered with a down like a cobweb.*
2. GUNDELIA (*Glabro*) Orientalis, acanthi aculeati folio, capite glabro. Tourn. Cor. 51. *Eastern Gundelia with a prickly Bear's-breech leaf, and a smooth head.*

This plant was discovered by Dr. Gundelscheimer, in company with Tournefort, near Baibout in Armenia, but has since been found growing naturally in several places in the Levant, where it is generally found in dry strong land. The stalks of this plant seldom rise more than a foot and a half high; the under leaves are long, narrow, and sawed on their edges, their teeth ending in a spine; the other leaves are broader, which are irregularly slashed to the midrib, and armed at the points with sharp prickles; the stalks divide upward into several branches, which are armed with leaves of the same form, but are narrower; and each is terminated by a conical head of flowers, resembling those of Fuller's Thistle, being surrounded at the base by a circle of long, narrow, prickly leaves: these heads are composed of many hermaphrodite florets, which are shut up in the scales, each having an empalement, and a germen with five stamina surrounding it; but there are few of the seeds which ripen perfectly in each head, in the natural places of its growth. If rain happens at the time when the plants are in flower, the germen perishes, which is the case with several other of those plants whose flowers are collected into heads.

These plants are propagated by seed, which should be sown the beginning of March, in a warm dry border of fresh, but lean earth, in the place where the plants are designed to remain. When the plants come up, they must be carefully cleared from weeds; as they grow large, they should be thinned, leaving the plants which are designed to remain, about two feet asunder, that they may have room to spread. After this there is no other culture required, but to keep them clear from weeds; and if the frost should prove severe in winter, the plants should be covered with straw or Peas-haulm to protect them, but this covering must be taken off in mild weather; in two years they will produce their flowers, when they will make a fine appearance amongst other hardy plants in the pleasure-garden. They flower in May, and the plants lose their stalks and leaves in autumn, but their roots will abide many years.

G Y P-

GYP SOPHYLA. Lin. Gen. Plant. 498. We have no English title for this genus.

The CHARACTERS are,

The flower hath a permanent, angular, bell-shaped empalement, cut into five parts at the top. It hath five oval blunt petals, which spread open, and ten awl-shaped stamina, terminated by roundish summits. In the center is situated a globular germen, supporting two slender styles, crowned by single stigmas. The germen afterward becomes a globular capsule with one cell, opening with five valves, filled with small roundish seeds.

This genus of plants is ranged in the second section of Linnæus's tenth class, which includes those plants whose flowers have ten stamina and two styles.

The SPECIES are,

1. **GYP SOPHYLA** (*Aggregata*) foliis mucronatis recurvatis, floribus aggregatis. Lin. Sp. Plant. 406. *Gypsophyla with pointed recurved leaves, and flowers gathered in a head. Lychnis Hispanica kali folio multiflora. Tourn. Inst. R. H. 338. Spanish Lychnis with a Glasswort leaf and many flowers.*
2. **GYP SOPHYLA** (*Fastigiata*) foliis lanceolato-linearibus, obsolete triquetris lævibus obtusis secundis. Lin. Sp. Plant. 407. *Gypsophyla with narrow spear-shaped leaves, having three blunt angles, and smooth obtuse leaves in clusters. Saponaria caule simplici, foliis linearibus ex alis foliorum confertis teretibus. Hort. Cliff. 166. Sopswort with a single stalk, very narrow leaves, coming out in clusters from the wings of the stalks.*
3. **GYP SOPHYLA** (*Prostrata*) foliis lanceolatis lævibus, caulibus diffusis, pistillis corollâ campanulatâ longioribus. Lin. Sp. Plant. App. 1195. *Gypsophyla with smooth spear-shaped leaves, diffused stalks, and the pointal longer than the petal, which is bell-shaped.*
4. **GYP SOPHYLA** (*Perfoliata*) foliis ovato-lanceolatis, semiamplexicaulibus. Lin. Sp. Plant. 408. *Gypsophyla with oval spear-shaped leaves, half embracing the stalks. Lychnis Orientalis, saponariæ folio & facie, flore parvo & multiplici. Tourn. Cor. 24. Eastern Lychnis with the leaf and appearance of Sopswort, having many small flowers.*
5. **GYP SOPHYLA** (*Paniculata*) foliis lanceolatis scabris, floribus dioicis corollis revolutis. Lin. Sp. Plant. 407. *Gypsophyla with rough, spear-shaped leaves, male and female in different plants, and the petals of the flowers recurved. Alfine frutescens caryophylli folio, flore parvo albo. Gerb. Shrubby Chickweed with a Clove Gilliflower leaf, and a small white flower.*

The first sort grows naturally in the south of France, Spain, and Italy, upon the mountains. This hath a perennial root, from which arise many narrow leaves

ending in acute points, which are recurved; the stalks rise about a foot high, garnished with narrower leaves placed opposite, and at some of the joints there are smaller leaves growing from the stalks in clusters; the upper part of the stalk divides into smaller branches, each being terminated by a close bunch of small white flowers. These appear in July, and are succeeded by small oval capsules, filled with small seeds.

The second sort is somewhat like the first, but the leaves are much narrower, and almost three-cornered; they are placed in clusters, which come out from the side of the stalk; the bunches of the flowers are smaller, and not so closely joined. This hath a perennial root, and grows naturally upon the Helvetian mountains.

The third sort hath a perennial root, from which arise smooth spear-shaped leaves in clusters; the stalks are near a foot long, but are prostrate on the ground; the flowers have a purplish cast, and the stamina are much longer than the petals of the flowers. This flowers in June and July, and the seeds ripen in autumn.

The fourth sort grows naturally in the Levant, and also in Spain. It hath a strong, fleshy, fibrous root, which strikes deep in the ground, sending up several thick, fleshy stalks, which rise near two feet high, garnished with oval spear-shaped leaves, which half embrace the stalks with their base; the upper part of the stalk divides into many smaller branches, which are terminated with loose bunches of small white flowers. These open in July, and the seeds ripen in autumn.

The fifth sort grows naturally in Siberia and Tartary, the seeds of it were sent me from Petersburg. This hath a perennial root, from which arise many branching stalks a foot and a half high, garnished with narrow smooth-pointed leaves, shaped like those of Gilliflowers; at the top of the stalks are produced loose clusters of very small white flowers, which appear at the same time with the former sorts, and the seeds ripen in the autumn.

These plants have no great beauty, so are rarely cultivated but in botanic gardens for the sake of variety.

They are propagated by seeds, which should be sown in a bed of light earth, and when the plants are fit to remove, they may be transplanted into the places where they are designed to remain, and will require no other culture but to keep them clean from weeds, for the roots will continue several years, and annually produce flowers and seeds.

H Æ M

H Æ MANTHUS. Tourn. Inst. R. H. 657. tab. 433. Lin. Gen. Plant. 394. *Dracunculoides.* Boerh. Ind. alt. 2. 226. [*Alisma*, of *Alma*, blood, and *Alis*, flos, a flower, i. e. Blood-flower.]

The CHARACTERS are,

The flower has a permanent empalement of six leaves, which is large, and shaped like an umbel. It hath one erect petal, which is cut into six parts, having a short angular tube, and six awl-shaped stamina, which are inserted in the petal,

but are longer, terminated by oblong prostrate summits. The germen is situated under the flower, supporting a single style the length of the stamina, crowned by a single stigma. The germen afterward becomes a roundish berry with three cells, each containing one triangular seed.

This genus of plants is ranged in the first section of Linnæus's sixth class, intitled Hexandria Monogynia, which includes the plants whose flowers have six stamina and one style.

H Æ M

The SPECIES are,

1. *HÆMANTHUS (Coccineus)* foliis linguiformibus planis lævibus. Prod. Leyd. 42. *Blood-flower with plain, tongue-shaped, smooth leaves.* *Hæmanthus Africanus.* H. L. Bat. *African Blood-flower, or Cape Tulip.*
2. *HÆMANTHUS (Carinatus)* foliis longioribus carinatis. *Blood-flower with longer keel-shaped leaves.*
3. *HÆMANTHUS (Puniceus)* foliis lanceolato ovatis undulatis erectis. Hort. Cliff. 127. *Blood-flower with spear-shaped, waved, erect leaves.* *Hæmanthus colchici* foliis perianthio herbaceo. Hort. Elth. 167. *Blood-flower with Meadow Saffron leaves, and an herbaceous involucre.* *Dracunculoides.* Boerh. Ind. alt. 2. 226. *Bastard Dragon.*

The first sort has been many years in several curious gardens in Europe, where it hath seldom flowered. This hath a large bulbous root, from which in the autumn comes out two broad flat leaves, of a fleshy consistence, shaped like a tongue, which turn backward on each side, and spread flat on the ground, so have a singular appearance all the winter; and in the spring these leaves decay, so that from the end of May to the beginning of August, they are destitute of leaves: when these produce their flowers, it is always in the autumn, just before the new leaves come out. In the books where this plant is figured, the flowers are represented growing upon a strong upright foot-stalk; but all those which I have seen in flower, never have risen more than two or three inches from the bulb, with a large cluster of bright red flowers, inclosed in a common leafy-coloured empalement; these were tubulous, with one petal cut into six parts, each having six long stamina, standing out beyond the petal, and in the center appears the germen sitting under the flower, supporting a single style, crowned with a stigma. The germen never ripens to a seed in England, but decays with the flower, and then the green leaves grow and spread on the ground.

The second sort hath a large bulbous root like the first, which sends out three or four leaves, that grow a foot long or more; these are not flat like those of the other, but are hollowed like the keel of a boat, and stand more erect than those of the former sort, but are not quite so broad; the flowers of this are like those of the first, but are of a paler red; this is certainly different from the other. I received the roots of this from Dr. Van Royen, professor of botany at Leyden.

The third sort hath roots composed of many thick fleshy tubers, which join at the top, where they form a head, out of which arises a fleshy spotted stalk, like that of the dragon, which spreads out at the top into several spear-shaped leaves, which are waved on their edges. The stalks grow about a foot high, and the leaves are six or eight inches long, and two broad in the middle; from the side of this stalk near the ground, breaks out a strong fleshy foot-stalk, about six or eight inches long, sustaining at the top a large cluster of flowers, included in one common empalement or covering, which is permanent; the flowers are shaped like those of the other sorts, but are of a yellowish red colour. These appear in May, June, or July, and are succeeded by berries which are of a beautiful red colour when ripe.

The two first sorts are with difficulty propagated in Europe, for their roots put out offsets but sparingly, so the gardens in Holland are supplied with them from the Cape of Good Hope, where they naturally grow, and produce seeds; the plants are too tender to thrive in this country in winter in the open air, therefore the roots must be planted in pots filled with light loamy earth, and, in the winter, placed in a dry glass-case, where, during that season, the leaves will be in full vigour, so will make a pretty appearance, when intermixed with other plants in the stove; and though they seldom flower here, yet are they worthy of a place in every garden where there is convenience of keeping them. The roots may be taken up when their leaves are decayed, and kept out of the ground till August, when they should be new pot-

ted, and may remain abroad till the end of September, at which time they may be removed into the glass-case; and during the time they are growing, will require to have frequent waterings, but it must not be given to them in large quantities.

If a border is made either against the front of the green-house or stoves, which may be contrived so as to be covered with glasses in winter, in which these roots, with the African Gladiolus's, Ixia's, Persian Cyclamens, &c. are planted in the full ground, they will flower more constantly, and the foot-stalks will rise much higher than those kept in pots.

The third sort is also a native of the Cape of Good Hope, from whence it was first brought to Holland, where it has been propagated and dispersed over Europe; this may be propagated by parting of the roots; the best time for this is in the spring, before the plants put out new stalks, which is also a right time to shift and new-pot them; but as the roots do not multiply very fast in offsets, the best way is to propagate them from seeds, which they ripen plentifully in England; these should be sown soon after they are ripe, in pots filled with light earth, and kept in the stove all the winter; if these pots are plunged into the tan-bed in the bark-stove, in the vacancies between the plants, the earth will be kept warm, and will not dry so fast, as when they are placed in a dry stove, so the seeds will be sooner prepared to vegetate; in the spring the pots may be taken out of the stove, and plunged into a hot-bed, which will bring up the plants; these must have air admitted to them every day in mild weather, to prevent their drawing up weak; and when they are fit to remove, they may be each planted in a separate small pot filled with light earth, and plunged into the hot-bed again, to promote their taking new root; then they must be gradually hardened, and afterward may be removed into the dry stove, where they should constantly remain, otherwise the plants will not thrive and flower in this country. In the winter season they must not have too much wet, for as their roots are fleshy and succulent, so they are apt to rot with moisture. In the summer they must have a large share of air in warm weather, and require to be frequently watered, especially during the time of their flowering.

HÆMATOXYLUM. Lin. Gen. Plant. 417. Bloodwood, Logwood, or Campeachy Wood.

The CHARACTERS are,

The flower hath a permanent empalement, which is cut into five oval segments. It hath five oval petals which are equal, and larger than the empalement, and ten awl-shaped stamina, which are longer than the petals, terminated by small summits. In the center is situated an oblong oval germen, supporting a single style, crowned by a thick indented stigma. The germen afterward becomes a compressed obtuse capsule, with one cell, opening with two valves, containing two or three oblong kidney-shaped seeds. This genus of plants is ranged in the first section of Linnæus's tenth class, intitled Decandria Monogynia, which includes those plants whose flowers have ten stamina and one style.

We have but one SPECIES of this genus, viz.

HÆMATOXYLUM (Campechianum). Hort. Cliff. 161. Logwood, Lignum Campechianum, species quædam. Sloan. Cat. Jam 213. *Campeachy Wood.*

This tree grows naturally in the Bay of Campeachy, at Honduras, and other parts of the Spanish West-Indies, where it rises from sixteen to twenty-four feet high. The stems are generally crooked, and very deformed, and are seldom thicker than a man's thigh. The branches come out on every side; they are crooked, irregular, and armed with strong thorns, garnished with winged leaves, composed of three or four pair of lobes, which are obtuse, and indented at the top. The flowers come out in a racemus from the wings of the leaves, standing erect; they are of a pale yellowish colour, with a purple empalement, and are succeeded by flat oblong pods, each containing two or three kidney-shaped seeds.

The

The wood of this tree is brought to Europe, where it is used for dyeing purples, and for the finest blacks, so is a valuable commodity; but the Spaniards, who claim a right to the possession of those places where it naturally grows, are for excluding all other countries from curing of the wood, which has occasioned many disputes with their neighbours, but particularly with the English; this it is to be hoped will soon be over, as there are some of the planters in Jamaica, and the other islands in America, belonging to the crown of Great-Britain, who have propagated this tree in so great plenty, as to have hopes of supplying the demand for this wood in Britain in a very few years; for the trees grow so fast there, as to be fit for use in ten or twelve years from seed; and as they produce great plenty of seeds in the British colonies, so those seeds scattering about, the plants come up in all the neighbouring lands, therefore will soon be like an indigenous plant of the country.

Some of the planters in Jamaica have inclosed their estates with hedges formed of these trees, which are very strong and durable; but where the hedges are cut, it will greatly retard the growth of the trees, so that those who propose to make an advantage by the propagation of the wood, should sow the seeds upon swampy lands, which may be unfit for growing of sugar, and permit all their branches to remain, which will be of great use in augmenting the bulk of their stems; and if, while the plants are young, they are kept clean from weeds, &c. it will be of great advantage in promoting of their growth. I have been credibly informed by some of the planters in Jamaica, that they have had some plants of this sort upward of ten feet high in three years, so that it requires but few years to raise a supply of this wood, sufficient to answer all the demands for it.

This plant is preserved in some curious gardens in England, for the sake of variety. The seeds are frequently brought from America, which, if fresh, readily grow when sown upon a good hot-bed; and if the plants are kept in a moderate hot-bed, they will grow to be upward of a foot high the same year, and, while the plants are young, they are generally well furnished with leaves; but afterward they make but little progress, and are frequently but thinly clothed with leaves. These plants are very tender, so should be constantly kept in the bark-stove, where, if they are duly watered, and the stove kept in a good degree of heat, the plants may be preserved very well. There are some of these plants now in England, which are upward of six feet high, and as thriving as those in their native soil.

HALESIA. Lin. Gen. Plant. 596.

The CHARACTERS are,

The flower hath a small permanent empalement of one leaf, indented in four parts; it hath a bell-shaped swelling flower of one petal, divided at the brim into four lobes, and from twelve to sixteen stamina, shorter than the petal, terminated by oblong erect summits; the germen is situated below, is oblong, supporting a slender style longer than the petal, crowned by a simple stigma; the germen afterward becomes an oblong nut, narrowed at both ends, having four angles, with two cells, inclosing a single seed in each.

This genus of plants is ranged in the first section of Linnæus's eleventh class, intitled Dodecandria Monogynia, the flower having twelve stamina and one style.

The SPECIES are,

1. **HALESIA** (*Tetraptera*) foliis lanceolato-ovatis, petiolis glandulosis. Lin. Sp. 636. *Halesia with oval spear-shaped leaves, whose foot-stalks are glandulous.* Frutex padi foliis serratis, floribus monopetalus albis campaniformibus, fructu crasso tetragono. Catseb. Hist. Carol. 1. p. 64.
2. **HALESIA** (*Diptera*) foliis ovatis, petiolis lævibus. Lin. Sp. 636. *Halesia with oval leaves having smooth foot-stalks.*

This genus of plants received its title from the late learned and reverend Doctor Hales, minister of Teddington, near Hampton-Court.

Both the sorts grow naturally in South-Carolina; the first on the banks of Santee river, where it frequently comes up with two or three stems from the same root, which rise from fifteen to twenty feet high, sending out branches toward their tops, garnished with oval spear-shaped leaves, sawed on their edges: the flowers are produced on the side of the branches in clusters, from two or three to six or seven in each; they are bell-shaped, hanging downward, of one petal, white, which is indented in four parts at the brim; these are succeeded by oblong nuts, having four wings and four cells, each containing one oblong seed.

The second sort hath much resemblance to the first, the leaves are oval, and the foot-stalks are smooth; the fruit has but two angles.

These plants are propagated by seeds, when they can be procured fresh from the places of their natural growth. These should be sown in pots as soon as the seeds arrive, plunging the pots into the ground, in a situation where they may have only the morning sun. The seeds often remain a year in the ground, therefore the earth in the pots should not be disturbed, until there is no probability of the seed growing. When the plants appear, they should be screened from the sun, and frequently, but not too plentifully watered; for while the plants are young, much moisture will rot their shanks. The following autumn, the pots should be placed in a common frame, where the plants may enjoy the free air in mild weather, and be screened from frost. The spring following, before the plants begin to shoot, they should be each put into a separate small pot, plunging them in a frame, where they should be shaded from sun; and in the summer placed in a shady situation, screening them in winter; and the spring following they may be turned out of the pots, and planted in the full ground where they are designed to remain.

HALICACABUM. See **PHYSALIS**.

HALICACABUS PEREGRINA. See **CARDIOSPERMUM**.

HALIMUS. See **ATRIPLEX**.

HALLERIA. Lin. Gent. Plant. 679. *Caprifolium.* Boerh. Ind. alt. 2. p. 226. *African Fly Honeyfuckle.*

The CHARACTERS are,

The flower hath a permanent empalement of one leaf, which is cut into three parts at the top, the upper segment being much broader than the other. It hath one petal of the grining kind. The bottom of the tube is roundish. The chaps are swollen and inflexed, the brim is erect and oblique, cut into four segments, the upper being longer than the others, and is blunt, with an indenture at the top; the two side ones are shorter, and pointed, the lower is very short and acute. It hath four stamina, which are bristly, two being longer than the other, terminated by twin summits. In the bottom of the tube is situated an oval germen, with a style longer than the stamina, crowned by a single stigma. The germen afterward becomes a roundish berry with two cells, each containing one hard seed.

This genus of plants is ranged in the second section of Linnæus's fourteenth class, intitled Didynamia Angiospermia, which includes the plants with a ringent flower, which have two long and two shorter stamina, and the seeds are included in a capsule.

We have but one SPECIES of this genus, viz.

HALLERIA (*Lucida*). Hort. Cliff. 323. This plant has its title from Dr. Haller, who was professor of botany at Gottingen, in Germany. *Caprifolium Africanum folio pruni leviter serrato, flore ruberrimo, baccâ nigra.* Boerh. Ind. alt. 2. 226. *African Fly Honeyfuckle, with a Plum leaf lightly sawed, a very red flower, and a black berry.*

The English name which I have here added, has been given to this plant by some gardeners, who observed that the shape of the flower had some resemblance to that of the Upright, or Fly Honeyfuckle, and for want of an English name gave this to it; or they might take it from the Latin name, by which it was called by Dr. Boerhaave, who made it a species of Honeyfuckle.

This

H A M

This plant grows to the height of six or eight feet, having a woody stem, which is well furnished with branches; these have oval sawed leaves, which are placed opposite, and continue green through the year; the flowers come out singly, and are of a red colour, but, being intermixed with the leaves, are not seen unless they are looked after, for they grow scatteringly on the branches; these come out in June, and the seeds ripen in September; the leaves are green in winter, so the plants make a variety in the green-house during that season.

It may be propagated by cuttings, which, if planted in pots filled with light earth in June, and plunged into a gentle hot-bed, will soon take root; these plants may be exposed in summer, and will require plenty of water in that season; in winter they must be housed with Myrtles, and other hardy exotic plants, which require a large share of air in mild weather.

HAMAMELIS. Lin. Gen. Plant. 155. Trilopus. Mitch. Gen. 22. *The Witch Hazel.*

The CHARACTERS are,
It is male and female in different plants; the male flowers have a four-leaved empalement, and four narrow petals, which are reflexed; they have four narrow stamina, which are shorter than the petals, terminated by horned reflexed summits. The female flowers have a four-leaved involucre, in which are four flowers; these have a four-leaved empalement, which is coloured; they have four narrow petals, which are reflexed, and four nectariums adhering to the petals. In the center is situated an oval hairy germen, supporting two styles, crowned by beaded stigmas. The germen afterward becomes an oval capsule sitting in the involucre, having two cells, each containing one hard, oblong, smooth seed.

This genus of plants is ranged in the second section of Linnæus's fourth class, but properly belongs to the second section of his twenty-second class, which includes those plants which have male and female flowers in different plants, whose female flowers have two styles.

We have but one SPECIES of this genus in the English gardens at present, viz.

HAMAMELIS (*Virginiana*). Flor. Virg. 139. *The Witch Hazel.* Pistachia Virginiana nigra, coryli foliis. Pluk. Alm. 296. *Black Virginia Pistachia with Hazel leaves.*

This plant grows naturally in North America, from whence the seeds have been brought to Europe, and many of the plants have been raised in the English gardens, where they are propagated for sale by the nursery gardeners. It hath a woody stem, from two to three feet high, sending out many slender branches, garnished with oval leaves, indented on their edges, having great resemblance to those of the Hazel Nut, placed alternately on the branches; these fall away in autumn, and when the plants are destitute of leaves, the flowers come out in clusters from the joints of the branches; these sometimes appear the latter end of October, and often not till December, but are not succeeded by seeds in this country.

As the flowers of this shrub make very little appearance, so it is only preserved in the gardens of the curious, more for the sake of variety than its beauty.

This is propagated by laying down the young branches in autumn, which will take root in one year, provided they are duly watered in dry weather; but many of the plants which are in the gardens, have been produced from seeds which came from America; these seeds always remain a whole year in the ground, so they should be sown in pots, which may be plunged into the ground in a shady part of the garden, where they may remain all the summer, and require no other care but to keep the pots clean from weeds, and in very dry weather to water them now and then; in autumn the pots may be removed to a warmer situation, and plunged into the ground under a warm hedge; and if the winter should prove very severe, they should have some light covering thrown over the pots, which will secure the seeds from being destroyed.

H A S

In the spring the plants will come up, therefore as the season grows warm, the pots may be removed where they may have the morning sun till eleven o'clock; and if they are duly watered in dry weather, the plants will have made good progress by autumn, when they should be transplanted, either into small pots, or in a nursery-bed, where in one, or at most two years time, they will be strong enough to plant where they are designed to remain; they love a moist soil, and a shady situation.

HAMELLIA. Lin. Gen. 232.

The CHARACTERS are,
The empalement of the flower is small, permanent, and cut into five acute segments; the flower is of one petal, having a long tube, whose brim is cut into five acute points; it hath five awl-shaped stamina inserted to the middle of the petal, terminated by linear summits the length of the petal; and an oval germen, whose lower point is conical, supporting a slender style the length of the corolla, crowned by an obtuse linear stigma: the germen afterward becomes an oval furrowed berry, with five cells, filled with small compressed seeds.

This genus of plants is ranged in the first order of Linnæus's fifth class, intitled Pentandria Monogynia, the flower having five stamina and one style: it is named in honour of Monsieur du Hamel des Monceaux, member of the Academy of Sciences at Paris, and fellow of the Royal Society of London; a gentleman well known to the learned, by the many useful books he has published.

We know but one SPECIES of this genus, viz.

1. **HAMELLIA** (*Patens*) racemis erectis. Jacq. Amer. 71. *Hamellia with erect spikes of flowers.*

This plant grows naturally in Africa, and also in the warm parts of America: I received the seeds from Paris, which were brought from Senegal by Mr. Adanson, with the title of Mortura on the paper; and before that, received a drawing of the plant in flower, from the late Dr. Houstoun, who found it growing naturally in America, where it has since been found growing by Mr. Jacquin, who has figured it.

It rises with a ligneous stalk five or six feet high, sending out several erect branches toward the top, garnished with oval woolly leaves, placed by threes round the branches, having red foot-stalks; the flowers terminate the branches in slender spikes; they are tubulous, and cut at their brims into five sharp segments, standing erect, of a bright red colour: these are not succeeded by seeds in England.

This plant is propagated by seeds, when they can be procured fresh from the countries where it grows naturally: these should be sown in small pots, and plunged into a moderate hot-bed: the plants generally appear in about five or six weeks after, and should then be treated in the same way as other plants from the same countries; giving them proper air in warm weather, and gently refreshing them with water; and when they are fit to transplant, they should be each planted in a small pot, plunging them into the hot-bed again, where they should be shaded from the sun until they have taken new root, when they should have air and moisture according to the warmth of the season. In the autumn the plants must be removed into the tan-stove, plunging the pots into the bed, where they should be always continued: this flowers in July and August, when it makes a pretty appearance.

As the seeds of this plant are seldom brought to England, so the plant may be propagated by cuttings, which if planted in small pots, plunged into a moderate hot-bed, and closely covered with either bell or hand-glasses, will put out roots in about six weeks, and may then be treated in the same way as the seedling plants.

HARMALA. See PEGANUM.

HASSELQUISTIA. Lin. Gen. 341.

The CHARACTERS are,
It is an umbelliferous plant, whose universal umbel is composed of six spreading rays; these are for the most part double; the greater involucre has many short brightly leaves;

leaves; the proper empalement is very small, and hath five indentures; the general umbel is half radiated; the outer flowers are fruitful, but those in the disk are barren; they have five petals, and five slender stamina longer than the petals, terminated by roundish summits: the turbinate germen is situated under the flower, supporting two slender recurved styles, crowned by obtuse stigmas; the germen afterward becomes an orbicular fruit, composed of two seeds having borders.

This genus of plants is ranged in the second order of Linnæus's fifth class, intitled Pentandria Digynia, the flowers having five stamina and two styles.

It is named after Mr. Hasselquist, who was a pupil of Dr. Linnæus.

1. HASSELQUISTIA (*Egyptiaca*). Amoen. Acad. 4. p. 370. *Egyptian Hasselquistia*. Pastinaca Orientalis, foliis eleganter incis. Buxb. Cent. 3. p. 16.

This plant is biennial, and being a native of warm countries, is with difficulty preserved in England; for when the plants come up early in the spring, they do not perfect their seeds the same year: and those plants which arise in the autumn, seldom live through the winter; therefore the surest method to procure good seeds in this country, is to sow the seeds in pots about the middle of August, placing the pots where they may have the morning sun only, being careful to water them duly; and as weeds will come up in the pots to take them out, and where the plants are too close, thin them; in October remove the pots into a common frame, where they may enjoy the free air in mild weather, but be screened from frost: in the spring following, if the plants are carefully turned out of the pots, and planted in the full ground, they will flower in June, and the seeds will ripen in August.

HAWTHORN. See MESPILUS.

HAZEL. See CORYLUS.

HEDERA. Lin. Gen. Plant. 249. Tourn. Inst. R. H. 612. tab. 384. *The Ivy-tree*.

The CHARACTERS are,

The flowers are disposed in form of an umbel, having a small involucre indented in many parts. The empalement is cut into five parts, and sits upon a germen. The flower hath five oblong petals, which spread open, whose points are incurved; they have five awl-shaped stamina, terminated by prostrate summits, which are cut into two at their base. The germen, which is situated below the flower, supports a short style, crowned by a single stigma. The germen afterward becomes a globular berry with one cell, inclosing four or five large seeds, convex on one side, and angular on the other.

This genus of plants is ranged in the first section of Linnæus's fifth class, which includes those plants whose flowers have five stamina and but one style.

The SPECIES are,

1. HEDERA (*Helix*) foliis ovatis lobatisque. Flor. Lapp. 91. *Ivy with oval lobed leaves*. Hedera arborea. C. B. P. 305. *Tree Ivy*; and the Hedera communis major. J. B. 2. 111. *Great common Ivy*.

2. HEDERA (*Quinquefolia*) foliis quinatis, ovatis, serratis. Hort. Cliff. 74. *Ivy with leaves composed of five lobes, which are sawed*. Vitis quinquefolia Canadensis scandens. Tourn. Inst. 613. *Climbing Canada Vine with five leaves, commonly called Virginia Creeper*.

The first sort grows naturally in moist parts of England, where it meets with any neighbouring support. The stalks will fasten to it, and rise to a very great height, sending out roots on every side, which get into the joints of walls, or the bark of trees, and thereby are supported; or if there is no support near, the stalks trail upon the ground, and take root all their length, so that they closely cover the surface, and are difficult to eradicate; for where any small parts of the stalks are left, they will soon spread and multiply. While these are fixed to any support, or trail upon the ground, their stalks are slender and flexible; but when they have reached to the top of their support, they shorten and become woody, forming themselves

into large bushy heads, and their leaves are larger, more of an oval shape, and not divided into lobes like the lower leaves, that it hath a different appearance, which has occasioned some to take them for distinct species.

In the latter part of the last century, when it was the fashion to fill gardens with all sorts of sheered Evergreens, there were many of these plants trained into round heads, which were clipped into balls, or in form of a cone; and as these were so hardy as not to be injured by weather, and would grow in any soil, so they were then much esteemed; but since that unnatural taste has been exploded, these plants are seldom admitted into gardens, unless to cover walls, or run over grottos, &c. for which purpose there is no plant so well adapted.

There are two varieties of this, one with silver-striped leaves, and the other with yellowish leaves on the top of the branches; these are preserved in some gardens for the sake of variety.

These plants are easily propagated by their trailing branches, which send forth roots their whole length; which branches being cut off, and planted, will grow in almost any soil or situation, and may be trained up to stems, or suffered to remain as climbers, to cover walls, pales, &c.

They may also be propagated by seeds, which should be sown soon after they are ripe, which is in the beginning of April: if these are kept moist and shaded, they will grow the same spring, otherwise they will remain a year in the ground; therefore few persons trouble themselves to propagate the plants in this way, the other being much more expeditious.

While the stalks of this plant trail, either on the ground or upon walls, or other support, they do not produce any flowers, which has occasioned its being called sterile, or barren Ivy; but when the branches get above their support, they produce flowers at the end of every shoot; these appear in September, and are succeeded by berries, which turn black before they are ripe, and are formed into round bunches, which are called corymbi, and from these the epithet of corymbus, so frequently used by botanists, is taken.

The leaves of this plant are frequently applied to issues to keep them cool, and free from inflammations; they are also used for curing of scabs, sores, and scald heads. Mr. Boyle, in his Usefulness of Experimental Philosophy, commends a large dose of the full ripe berries, as a remedy against the plague; but Schroder says, they purge upward and downward. The gum of Ivy is caustic, but is recommended by some to take spots and freckles out of the face.

There is mention made of another species of Ivy, which is titled Hedera Poetica, by Caspar Bauhin; this grows in many of the islands of the Archipelago, and produces yellow berries; but as I have not seen this plant, I cannot determine if it is a distinct species. Dr. Linnæus supposes it to be only a variety, though he has not seen the plant; but Tournefort, who gathered it in the Levant, puts it down as a different sort.

The second sort grows naturally in all the northern parts of America; it was first brought to Europe from Canada, and has been long cultivated in the English gardens, chiefly to plant against walls, or high buildings to cover them, which these plants will do in a short time, for they will shoot almost twenty feet high in one year, and will mount up to the top of the highest building; but as the leaves fall off in autumn, the plants make but an indifferent appearance in winter; and as it is late before they come out in the spring, they are not much esteemed, unless it is for such situations, where better things will not thrive; for this plant will thrive in the midst of London, and is not injured by smoke, or the closeness of the air, so are very proper for such situations. The stalks of these plants put out roots, which fasten themselves

into the joints of the walls, whereby they are supported.

This may be propagated by cuttings, which if planted in autumn on a shady border, will take root, and by the following autumn will be fit to plant where they are designed to remain.

HEDERA TERRESTRIS. See **GLECHOMA.**

HEDGES. Hedges are either planted to make fences round inclosures, or to part off and divide the several parts of a garden: when they are designed as outward fences, they are planted either with Hawthorn, Crabs, or Black Thorn, which is the Sloe; but those Hedges which are planted in gardens, either to surround wilderness quarters, or to screen the other parts of a garden from sight, are planted with various sorts of plants, according to the fancy of the owner; some preferring ever-green Hedges, in which case the Holly is best, next the Yew, then Laurel, Laurustinus, Phillyrea, &c. others, who make choice of the deciduous plants, prefer the Beach and Hornbeam, English Elm, or the Alder, to any other; I shall first treat of those Hedges which are planted for outside fences, and afterward briefly touch on the other.

These Hedges are most commonly made of Quick, yet it will be proper, before planting, to consider the nature of the land, and what sorts of plants will thrive best in that soil, whether it be clay, gravel, sand, &c. likewise what the soil is from whence the plants are to be taken; for if the land they are taken from is much better than that in which they are to be planted, it will be more difficult to get them to grow. As for the size, the sets ought to be about the bigness of a goose quill, and cut within about four or five inches of the ground; they should be fresh taken up, strait, smooth, and well rooted. Those plants which are raised in the nursery, are to be preferred to all others, and if raised on a spot near the place, it will be best.

Secondly, If the Hedge has a ditch, it should be made six feet wide at top, and one foot and a half at bottom, and three feet deep, that each side may have a proper slope; for when the banks are made too upright, they are very subject to fall down after every frost or hard rain; besides, if the ditches are made narrower, they are soon choked up in autumn by the falling leaves, and the growth of weeds, nor are they a sufficient fence to the Hedge against cattle, where they are narrower.

Thirdly, If the bank be without a ditch, the sets should be set in two rows, almost perpendicular, at the distance of a foot from each other, in the quincunx order, so that in effect they will be but six inches asunder.

Fourthly, The turf is to be laid with the Grass side downwards, on that side of the ditch the bank is designed to be made, and some of the best mould should be laid upon it, to bed the Quick; then the Quick is to be planted upon it a foot asunder, so that the ends of the Quick may stand upright.

Fifthly, When the first row of Quick is planted, it must be covered with mould, and the turf laid upon it as before; so that when the bank is a foot high, you may plant another row of sets against the spaces of the lower Quick, and cover them as the former was done; and the bank is to be topped with the bottom of the ditch, and a dry, or dead Hedge laid on the other side, to defend the under plantation from the cattle.

In making of these dead Hedges, there should be stakes driven into the loose earth, at about two feet and a half distance, so low as to reach the firm ground.

Oak stakes are accounted the best, and Black Thorn and Sallow the next; then let the small bushes be laid at bottom, but not too thick, for that will cause the bushes to rot; but the upper part of the Hedge should be laid with long bushes to bind the stakes in with, by interweaving them.

And, in order to render the Hedge yet stronger, you

may edder it (as it is called,) i. e. bind the top of the stakes in with some small long poles, or sticks on each side; and when the eddering is finished, drive the stakes anew, because the waving of the Hedge and eddering is apt to loosen the stakes.

The Quick must be constantly kept weeded, and secured from being cropped by the cattle, and in February it will be proper to cut it within an inch of the ground, if it was not done before; which will cause it to shoot strong, and help it much in the growth.

When a Hedge is of about eight or nine years growth, it will be proper to plash it; the best time for this work is either in October or February.

When a Hedge is grown old; i. e. of about twenty or thirty years growth, and there are in it old stubs as well as new shoots, the old stubs should be cut sloping off within two or three inches of the ground, and the best and longest of the middle size should be left to lay down; and some of the strongest, at the height of five or six feet, according as you design the height of the Hedge to be, may be left to serve instead of stakes, and fresh stakes should be put in those places where they are wanting; the Hedge should be then thinned, so as to leave on the stubs only such shoots as are designed to be of use, that there may be room left to put a spade in between them; the ditch also should be cleansed, and each side of the slopes kept as in a new ditch; and where the earth is washed from the roots of the Quick, or is hollow, face it anew with so much of the first spit of earth that is dug out of the ditch, as there is occasion for, and lay what is dug out at the second spit, on the top of the bank; for if it be laid on the side, or face of the bank, it will slip into the ditch again when wet comes, and also take a great deal of the bank along with it.

In plashing Quicks, there are two extremes to be avoided; the first is, laying it too low and too thick; because it makes the sap run all into the shoots, and leaves the plashes without nourishment, which, with the thickness of the Hedge, kills them.

Secondly, It must not be laid too high, because this draws all the sap into the plashes, and so causes but small shoots at the bottom, and makes the Hedge so thin, that it will neither hinder the cattle from going through, nor from cropping of it.

When the shoot that is designed to be plashed is bent, give it a small cut with a bill, half through, sloping a little downwards, and then weave it about the stakes; and when the whole is finished, trim off the small superfluous branches that straggle too far out on both sides of the Hedge.

If the stubs are very old, cut them quite down, and secure them with good dead Hedges on both sides, till the young shoots are got up tall enough to plash, and plant new sets in the void spaces.

In making a Hedge, if it be set with Crab Stocks, it will be proper to leave one standing uncut up at every thirty or forty feet, if the ground on both sides of the Hedge be your own; which being done, they may be so ordered, by pruning or staking, that one may lean into one ground, and the other into another, &c.

These stocks should be pruned up every year, till they are brought out of the reach of the cattle, and then they may be grafted with the Red Streak, Gennet-moil, or what other kind of cyder Apple you please.

If the stocks be of Apple kernels, they may stand ungrafted, for many of them will yield very good cyder fruit; but then such stocks as are not grafted, will be longer before they bear; and also when you do graft, you may be certain of your kind; but if you find a very natural stock, which by leaf, shoot, and bud, appears likely, you may try it, and so you may have a new fine fruit; and if you do not like it, you may graft it when you please.

As for the rest of the Hedge, when it has shot four or five years, you may lay it to make a fence for the doing of which, take the following directions:

H E D

First, At every laying to lay down some old plashes; or, if the Hedge be thin, young ones; but they must be so laid, as to point with their ends to the ditch side of the bank, the ends being kept low on the bank; by being so ordered, they will the better thicken the bottom of the Hedge, and keep up the earth of the bank.

Secondly, To heighten the bank every time you lay earth on it, so as to cover the layers, all but the ends, this earth will very much help the Quick; and by heightening the banks, and deepening the ditch, you will render the fence the better.

Thirdly, Not to cut the plashes too much, but just so as they may bend down well; nor to lay them too upright, as some do, but to lay them near to a level; for by so doing, the sap will the better break out at several places, and not run so much to the ends, as it will when they lie too much upon the slope.

If you have much wood to spare, you may cut up great part of those that grow near the ditch, but then you ought to hang the bank with bushes, to prevent cattle from cropping them the first year; these will shoot strong, secure the Hedge, keep up the bank, and thicken the bottom of the Hedge.

Fourthly, Take care to lay the Hedge pretty thick, and turn the beard on the ditch side; but you must not let the beard hang uncut (though it makes a good shew at the first making), but you must cut off all the straggling boughs within half a foot of the Hedge on both sides, which will cause it to shoot strong at these places, and make the Hedge much the thicker.

Fifthly, If the bank be high, make the Hedge so low, that it may just serve for a fence the first year, for it will soon grow higher; and the lower the Hedge is made, the faster the Quick will grow, and also will be the thicker at the bottom; but care must be taken to preserve it from cattle on the field side for the two first years that it is made.

Sixthly, If you would have a good Hedge, or fence, you should new lay it once in fourteen or fifteen years, and constantly root out Elder, Travellers Joy (which some call Bull-bine), Briony, &c. and do not leave too many high standards, or pollards in it, though the Elm is one of the best; also no dead wood is to be left in the bottom of the Hedges, for that will choke the Quick; but if there be a gap, the dead Hedge should be made at a distance.

The Crab is also frequently planted for Hedges, and if the plants are raised from the kernels of the small wild Crab, they are much to be preferred to those which are raised from kernels of all sorts of Apples without distinction; because the plants of the true small Crab never shoot so strong as those of the Apples, so may be better kept within the proper compass of a Hedge; and as they have generally more thorns upon them, they are better guarded against cattle, &c. than the other; besides, the plants of the Crab will grow more equal than those which are raised from the kernels of various kinds of Apples, for these always produce a variety of plants, which differ from each other in their manner of growth, as much as in the size and flavour of their fruits; so that Hedges made of these will not appear so well, nor can be so well managed as the other.

Some persons intermix Crab with the White Thorn in their Hedges, but this is not a good method; for the plants of the Crab will grow much stronger than those of the White Thorn, so that the Hedge will not be of equal growth; which is not near so beautiful or useful, as when the plants of a Hedge keep pace in their growth.

The Black Thorn, or Sloe, is also frequently planted for Hedges, and is a strong durable plant for that purpose, especially as it is so strongly armed with thorns, that cattle seldom care to browse upon it; but where this is planted, the best way is to raise the plants from the stones of the fruit; for all those which are taken from the roots of old trees, spawn, and put out suckers in such plenty from their roots, as to spread over, and fill the neighbouring ground to a consider-

H E D

able distance on each side of the Hedge; and this plenty of suckers drawing away the nourishment from the old plants of the Hedge, they never grow so well as where there are few or no suckers produced, which those plants which are propagated from the stones send not forth, or at least but sparingly, therefore may with little trouble be kept clear of them. The best method of raising these Hedges is, to sow the stones in the place where the Hedge is intended (where it can be conveniently done), for then the plants will make a much greater progress than those which are transplanted; but the objection to this method will arise from the difficulty of securing the young plants from the cattle; but this can have little force, when it must be considered, that if the Hedge is planted, it must be fenced for some years, to prevent the cattle from destroying it; therefore the same fence will do for it when sown, nor will this require a fence much longer than the other. For the plants which stand unremoved, will make a better fence in seven years, than that which is planted, though the plants should be of three or four years growth when planted; which is what I have seen two or three times, where the experiment has been tried. The stones of this fruit should be sown early in January, if the weather will permit; but when they are kept out of the ground longer, it will be proper to mix them with sand, and keep them in a cool place. The bushes of the Black Thorn are by much the best of any for making of dead Hedges, being of longer duration, and having many thorns, neither the cattle nor the Hedge-breakers, will care to meddle with them; these bushes are also the best to be used for under ground drains, for the draining of land, for they will remain sound a long time when the air is excluded from them.

The Holly is sometimes planted for Hedges, and is a very durable strong fence; but where it is exposed, there will be great difficulty to prevent its being destroyed, otherwise it is by far the most beautiful plant, and being an Evergreen, will afford much better shelter to cattle in winter, than any other sort of Hedge; and the leaves being armed with thorns, the cattle will not care to browse upon it. Another objection to this plant is the slow growth, so that Hedges planted with this plant, require to be fenced a much longer time than most others. This is a reason which must be admitted, to prevent this being generally practised; but in such grounds as lie contiguous to, or in sight of gentlemen's houses, these sort of Hedges will have an exceeding good effect, especially when they are well kept, as they will appear beautiful at all seasons of the year; and in the spring of the year, when the sharp winds render it unpleasant to walk abroad in exposed places, these Hedges will afford good shelter, as they will effectually keep off the cold winds, if they are kept close and thick. The surest method of raising these Hedges is, by sowing the berries in the place where they are to stand; but these berries should be buried in the ground one year before they are sown, by which method they will be prepared to grow the following spring. The way of doing this is, to gather the berries about Christmas (which is the time they are usually ripe,) and put them into large flower-pots, mixing some sand with them; then dig holes in the ground, into which the pots must be sunk, covering them over with earth about ten inches thick; in this place they may remain till the following October, when they should be taken up, and sown in the place where the Hedge is intended. The ground for this Hedge should be well trenched, and cleared from the roots of all bad weeds, bushes, trees, &c. Then two drills should be made at about a foot distance from each other, and about two inches deep, into which the seeds should be scattered pretty close, lest some should fail; for it is better to have too many plants come up, than to want. The reason of my advising two drills is, that the Hedge may be thick to the bottom, which in a single row rarely happens, especially if there is not great care taken of them in the beginning. When the plants come up, they must be carefully weeded; for if the weeds

weeds are permitted to grow among them, they will soon destroy them, or weaken them so much, that they will not recover their strength in a long time. This should be constantly observed, by every person who is desirous to have good Hedges of either sort; for when the weeds are suffered to grow near the plants, they will not only rob them of a great part of their nourishment, but also prevent their putting out shoots near the ground, which will occasion the bottom of the Hedge to be thin and naked.

When these Holly Hedges are designed to be kept very neat, they should be sheered twice a year, in May and August; but if they are only designed as fences, they need not be sheered oftener than once a year, which should be about the latter end of June, or the beginning of July; and if this is well performed, the Hedges may be kept very beautiful.

The fences which are made to secure these Hedges from cattle while they are young, should be contrived so as to admit as much free air as possible, which is absolutely necessary for the growth of the plants; for when they are crowded on each side with dead Hedges, the plants seldom thrive well. The best sort of fences for this purpose, are those which are made with posts and rails; or instead of rails, three ropes drawn from post to post, and holes made in the posts to draw the ropes through; this is the cheapest fence of this kind, and will appear very handsome; but if sheep are not admitted into the fields, there will be occasion for two ropes only, which will be enough to keep off larger cattle; and if the ropes are painted over with a composition of melted pitch, brown Spanish colour, and oil, mixed well together, they will last sound several years; and these sort of fences never obstruct the air, and the place, at the same time being open to view, the weeds will be better discovered than when the fences are close. In the latter case, the Hedges are sometimes suffered to be over-run with weeds, by their being excluded from the sight, so are frequently forgotten, especially in moist weather, when the weeds grow more luxuriant.

There are some persons who intermix Holly with the White Thorn in making their Hedges, which if rightly managed, will have a good effect, especially when young; but when this is practised, the Holly should be planted so near, as that the Hedge may be entirely formed of it as it grows up, when the White Thorn should be quite rooted out; for as these advance, they will not keep pace in their growth, so will not appear beautiful when intermixed.

When a Hedge of Holly is intended to be made by plants, the ground should be well trenched, as was before advised for the seeds; and (unless the ground be very wet) the plants should be set in October, but, in wet ground, March is preferable. The plants should not be taken from a better soil than that in which they are to be planted; for when it so happens, the plants are much longer before they recover this change, than those are which are taken from a leaner soil. If the plants have been before removed two or three times, they will have better roots, and will be in less danger of miscarrying; besides, they may be removed with balls of earth to their roots. When the frost comes on, if mulch be laid upon the ground near the roots of the plants, it will prevent the tender fibres, which may then have been put out, from being destroyed by the cold. I would never advise the planting of Hedges with Holly plants, of above five or six years growth from the berries; for when the plants are older, if they take to grow, they are longer before they form a good Hedge, than plants which are much younger; and if the plants have been twice before transplanted, they will more certainly grow.

I shall next treat of Hedges for ornaments in gardens: these are sometimes planted with Evergreens, especially if they are not intended to grow very high; in which case, they are planted with deciduous trees. Evergreen Hedges are planted with Holly, Yew,

Laurel, Laurustinus, Phillyrea, Alaternus, evergreen Oak, and some others of less note. The Holly is preferable to any other, for the reasons before given. Next to this, most people prefer the Yew, on account of its growing very close; for when these Hedges are well kept, they will be so thick as that a bird cannot get through them; but the dead colour of the Yew, renders these Hedges less agreeable. The Laurel is one of the most beautiful greens of any of the evergreen trees, but then it shoots so luxuriant, as to render it difficult to keep the Hedges which are planted with it, in tolerable shape; besides, the leaves being very large; if the Hedge is clipped with sheers, the leaves will be cut through, which gives them a bad appearance; therefore where there are Hedges of this kind, it will be the best way to prune them with a knife, cutting the shoots just down to a leaf. And although by this method the Hedge cannot be rendered so even as when cut with sheers, yet it will have a much better appearance than that of most of the leaves being cut through and stubbed, in the manner they must be when sheered.

The Laurustinus is also a very fine plant for this purpose, but the same objection is to be made to this as hath been to the Laurel; and as one of the great beauties of this plant is in its flowers, which are produced in the winter and spring, so when these are sheered, the flowers are generally cut off, by which their beauty is lost. Nor can this be avoided, where the Hedge is to be kept in close order, therefore this plant is not so proper for the purpose; but in such places where walls or other fences are designed to be hid, there is not any plant better adapted than this, provided it is rightly managed; for the branches of this plant are slender and pliable, so may be trained up close to the fence, whereby it may be entirely covered; and if, instead of clipping these with sheers, they are pruned with a knife, they may be so managed, as to have them full of flowers from the ground upward. This may be effected by pruning them in April, when the flowers are going off, cutting out those shoots that have flowered, or project too far from the fence; always cutting close to the leaf, that no stubs may be left: but those new shoots of the same spring must by no means be shortened, because the flowers are always produced at the extremity of the shoots of the same year; therefore when these are topped, as they must be by sheering, there can be few or no flowers upon these plants, except toward the top, where the sheers have not passed. By this method of knife pruning, the leaves will also be preserved entire, and the Hedge may always be kept enough within compass; and so thick, as fully to answer the purpose of covering the fence; and by the shoots growing a little irregular, it will make a much better appearance than any thorn Hedge whatever.

The small leaved and the rough leaved Laurustinus are the best sorts for this purpose, because their branches grow closer together than those of the shining leaved; they are also more hardy, and flower much better than the other, when growing in the open air.

The True Phillyrea is the next best plant for Hedges; it is by the gardeners called the True Phillyrea, to distinguish it from the Alaternus, which they simply call the Phillyrea. The branches of this are strong, the leaves pretty large, and of a strong green colour. And as this is a plant of middling growth, the Hedges planted with this may be led up to the height of ten or twelve feet; and if these Hedges are kept narrow at the top, that there may not be too much width for the snow to lodge upon them, they may be rendered very close and thick, and being a very good green, will make a fine appearance.

The Alaternus was formerly much more cultivated in the English gardens than at present. This was often planted to form Hedges, but the branches of this plant are too pliant for this purpose, being frequently displaced by strong winds, which render these Hedges unsightly; they also shoot very irregular and thin, so that

that the middle of the Hedge is frequently open and wide, and only the sides of them can be kept tolerably close, and that must be by often clipping them. If we add to this, their being frequently laid or broken down by snow in the winter, it must be deemed an improper plant for this purpose.

The Ilex, or evergreen Oak, is also planted for Hedges, and where these are designed to grow pretty tall, it is a fit plant for the purpose; because it is a plant of large growth, especially the sort which is most common in England; for there are two sorts of them which grow in the south of France and Italy, that are of much humbler growth, so are better adopted to this purpose, especially where the Hedge is not intended to be high, but these are not at present common here. When these Hedges are planted very young, and kept close trained from the beginning, they may be very close from the ground to the height of twenty feet or more; but these must always be kept narrower at the top than below, that there may not too much snow lodge upon them in the winter, which is apt to break and displace the branches, whereby the Hedges will be rendered unsightly.

There are also some persons who have planted the Pyracantha, or evergreen Thorn, Juniper, Box, Cedar of Virginia, Bay, &c. as also the Halimus, or Sea Purslane, and the Furz, Rosemary, and several other plants for Hedges; but the five sorts first mentioned having very pliant branches, which will require to be supported, and the three last being often destroyed by severe frost, renders them unfit for this purpose; nor are there other sorts of evergreen plants in the English gardens, which are so well adapted for Hedges, as those before-mentioned.

The deciduous trees, which are usually planted to form Hedges in gardens, are the following sorts.

The Hornbeam is much esteemed for this purpose, especially in such places where they are not required to be very high, or not wanted to grow very fast; for this plant, while young, doth not make so great progress as many others; but as it is of slower growth, the Hedges may be kept neat with less trouble than most other plants will require; and the branches naturally growing very close, they will make one of the closest Hedges of all the deciduous trees; but as the leaves of this tree continue upon the branches all the winter, and until the buds in the spring force them off, they have a bad appearance during the winter season.

The Beech is also a very proper tree for this purpose, having the same good qualities as the Hornbeam; but the leaves of this continue late in winter upon the branches, when they will have a bad appearance; besides, the litter which is occasioned by their leaves gradually falling most part of the winter, prevents the garden from being made clean a great while longer than if there are none of these trees planted.

The small-leaved English Elm, is also a proper tree for tall Hedges; if these are planted young, and kept closely clipped from their first setting out, the Hedges may be trained up to the height of thirty or forty feet, and be very close and thick the whole height. But when these trees are planted for this purpose, they should not be crowded so close together as they usually are by most people; by which method, when the trees have stood some years, if they have thriven well, their stems will approach so near each other, as that few branches can be maintained below, whereby the bottom of the Hedge will be naked; therefore they should not be planted closer together than seven or eight feet, or if they are ten feet it will be still better. And although at this distance they will not form a close Hedge so soon as when the trees are planted closer together, yet they will in a few years recompense for that, by their growing much closer and better from the ground upward.

The Dutch Elm was formerly in great esteem for Hedges, being quick of growth, and thriving in such soils as the English Elm would not grow; but the wretched appearance which these Hedges made, after

they had been growing a few years, very justly occasioned their being almost universally rooted out of gardens; for a more abominable plant was never introduced into gardens than this.

The Lime-tree hath also been recommended for Hedges, and in some of the old gardens there were many planted with this tree, which, for a few years after planting, made a tolerable appearance, especially when they grow upon a moist soil; but after they had stood some years, they grew very thin at bottom, and by being sheered at the top, they were rendered very stubby and unsightly, their leaves growing very thinly upon the branches, and these frequently turning of a black disagreeable colour, and falling off very soon in the autumn, and sometimes in the summer in dry seasons, has brought these trees so much into disrepute, as that few persons make use of them at present for this purpose: nor should any of the very strong shooting trees be applied to this use; for the more they are cut, the stronger they will shoot, and of course will appear very unsightly; besides, the often cutting of these Hedges occasions great trouble and expence, and frequent litters in gardens.

The Alder is frequently planted for Hedges, and where the soil is moist, there is not any of the deciduous trees equal to it for this purpose; for the leaves are of a lively green, continuing fresh till late in the autumn; and when they decay, their litter is soon over, for they all drop in a short time.

There are, besides the trees before-mentioned, many of the flowering shrubs which have been planted to form Hedges; such as Roses, Honeysuckles, Sweetbriar, &c. but these make a bad appearance, being more difficult to train; and if they are cut to keep them within compass, their flowers, which are their greatest beauty, will be entirely destroyed. But as these are but of low growth, they are not proper to plant where the Hedges are to be of any height.

Although I have given these full directions for planting and ordering of these Hedges for the pleasure-garden, yet I am far from recommending them as ornamental or useful. But as there are numbers of persons who may differ from me in their opinion, and therefore might think it a deficiency in my book, had I not given these instructions; to avoid their reproach, I have inserted as much as I think will be necessary for the obtaining these Hedges wherever they are desired, and at a less expence than the late method of planting them hath been generally attended with; where it is not uncommon to see four times the number of trees planted in these Hedges as would have been necessary, or that can remain long close together with any beauty. But most people who plant, are in too great a hurry to have their garden filled; and therefore frequently plant so close, as that in three or four years (if their trees thrive) three-fourths of them will require to be taken away again, to make room for those which are left to grow; and there are not wanting persons, who are ready enough to encourage this practice, since their own interest is thereby promoted.

The taste in gardening having been greatly altered of late years for the better, these clipped Hedges have been almost excluded; and it is to be hoped, that a little time will entirely banish them out of the English gardens, as it has already been done by the thorn Evergreens, which, a few years since, were esteemed the greatest beauties of gardens. The latter was introduced by the Dutch gardeners, and that of tall Hedges with treillage-work, was in imitation of the French gardens; in some of which, the expence of the iron treillage, to support the trees which compose their cabinets, pavillions, bowers, porticoes, and other pieces of rural architecture, amounted to a very great sum. I have been informed this work, in one garden, has cost above twenty thousand crowns; and this only to train up trees in the distorted shape of pilasters, niches, cornices, pediments, &c. when at the same time, these can no longer retain the forms in-

tended, than they are kept closely shorn into them; for no sooner do the trees begin to make fresh shoots, but the whole frame is altered; and instead of carrying the fine finished appearance of a regular piece of architecture, it is grown into a rude unpolished form. This expensive sort of work never has made much progress in England, but that part of the French taste, in surrounding all the several divisions of gardens with tall clipped Hedges, making great alleys, forming the walks into stars, and the like stiff performances, have too much obtained for some years past in England: and the taller these clipped Hedges were, the more they were admired; though many times they shut out from the view the sight of some of the noblest Oaks, and other timber trees, growing in the quarters, which are infinitely more pleasing to a person of true taste, than all the ridiculous forms it is possible for trees to be framed in by art. Besides, when the expence of keeping these Hedges, together with the great litter they occasion when clipped, is considered, these, added to many other reasons which might be given, are sufficient to exclude them out of gardens; where they can never be esteemed necessary, but to shut out from the view the sight of worse objects.

HEDYPNOIS. See HYOSERIS.

HEDYSARUM. Lin. Gen. Plant. 793. Tourn. Inst. R. H. 401. tab. 225. French Honeyfuckle.

The CHARACTERS are,

The flower hath a permanent empalement of one leaf, cut into five segments at the top. It is of the butterfly kind, having an oblong compressed standard, which is indented at the point and reflexed; the wings are oblong and narrow; the keel is compressed, broader at the end, but convex at the base. It hath nine stamina joined, and one standing separate, which are terminated by roundish compressed summits; the stamina are reflexed, having an angle or knee. In the center is situated a long narrow germen, supporting an awl-shaped inflexed style, crowned by a single stigma. The germen afterward becomes a jointed pod which is compressed, each joint being roundish, and incloses a single kidney-shaped seed.

This genus of plants is ranged in the third section of Linnæus's seventeenth class, intitled Diadelphia Decandria, which includes those plants whose flowers have ten stamina joined in two bodies.

The SPECIES are,

1. HEDYSARUM (*Coronarium*) foliis pinnatis, leguminibus articulatis aculeatis, nudis, rectis, caule diffuso. Hort. Cliff. 365. French Honeyfuckle with winged leaves, naked, prickly, jointed pods, and a diffused stalk. Hedysarum clypeatum, flore suaviter rubente. H. Eyst. French Honeyfuckle, with a delicate red flower.
2. HEDYSARUM (*Spinosissimum*) foliis pinnatis, leguminibus articulatis, aculeatis tomentosis, caule diffuso. Hort. Upsal. 231. French Honeyfuckle with winged leaves, jointed, prickly, woolly pods, and a diffused stalk. Hedysarum clypeatum minus, flore purpureo. Raii Hist. Smaller French Honeyfuckle with a purple flower.
3. HEDYSARUM (*Canadense*) foliis simplicibus ternatisque, floribus racemosis. Hort. Cliff. 232. French Honeyfuckle with single and trifoliate leaves, and flowers in bunches. Hedysarum triphyllum Canadense. Cornut. Three-leaved French Honeyfuckle of Canada.
4. HEDYSARUM (*flexuosum*) foliis pinnatis, leguminibus articulatis, aculeatis, flexuosis, caule diffuso. Lin. Sp. Plant. 750. French Honeyfuckle with winged leaves, jointed prickly pods which are waved, and a diffused stalk. Hedysarum annuum, siliquâ asperâ undulatâ intortâ. Tourn. Annual French Honeyfuckle, with a rough, waved, writhed pod.
5. HEDYSARUM (*Diphyllum*) foliis binatis petiolatis, floralibus sessilibus. Flor. Zeyl. 291. French Honeyfuckle with two leaves upon a foot-stalk, sitting close to the stalks. Hedysarum minus diphyllum, flore luteo. Sloan. Cat. 73. Smaller two-leaved French Honeyfuckle, with a yellow flower.
6. HEDYSARUM (*Purpureum*) foliis ternatis, foliolis obovatis floribus paniculatis terminalibus, leguminibus intortis. French Honeyfuckle with trifoliate oval leaves, flowers growing in panicles at the ends of the stalks, and

intorted pods. Hedysarum triphyllum fruticosum, flore purpureo, siliquâ varie distortâ. Sloan. Cat. 73. Three-leaved shrubby French Honeyfuckle, with a purple flower and a variously distorted pod.

7. HEDYSARUM (*Canescens*) foliis ternatis subtus nervosis, caule glabro fruticoso floribus spicatis terminalibus. Three-leaved shrubby dwarf Honeyfuckle, with veins on the under side, a smooth shrubby stalk, with flowers growing in spikes at the ends. Hedysarum triphyllum fruticosum supinum, flore purpureo. Sloan. Cat. Three-leaved shrubby dwarf French Honeyfuckle, with a purple flower.
8. HEDYSARUM (*Sericeum*) foliis ternatis, foliolis ovatis subtus sericeis, floribus spicatis alaribus terminalibusque. Three-leaved French Honeyfuckle, with oval leaves sitting on their under side, and flowers in spikes from the side and the end of the stalks. Hedysarum triphyllum frutescens, foliis subrotundis & subtus sericeis, flore purpureo. Houst. Three-leaved shrubby French Honeyfuckle with roundish leaves, which are silky underneath, and a purple flower.
9. HEDYSARUM (*Villosum*) foliis ternatis, caulibus diffusis villosis, floribus spicatis terminalibus, calycibus, villosissimis. Three-leaved French Honeyfuckle, with diffused stalks which are hairy, flowers growing in spikes at the ends of the branches, and very hairy empalements. Hedysarum triphyllum humile, flore conglomerato calyce villoso. Houst. Dwarf three-leaved French Honeyfuckle, with flowers growing in clusters, and a hairy cup.
10. HEDYSARUM (*Procumbens*) foliis ternatis caulibus procumbentibus racemosis, floribus laxè spicatis terminalibus, leguminibus contortis articulis quadrangularibus. Three-leaved French Honeyfuckle, with branching trailing stalks, flowers growing in loose spikes at the ends of the branches, and twisted pods with square joints. Hedysarum triphyllum procumbens, foliis rotundioribus & minoribus, siliquis tenuibus & intortis. Houst. Trailing three-leaved French Honeyfuckle, with smaller and rounder leaves, and narrow contorted pods.
11. HEDYSARUM (*Intortum*) foliis ternatis, foliolis obcordatis, caule erecto triangulo villoso, racemis terminalibus, leguminibus articulatis incurvis. French Honeyfuckle, with trifoliate leaves whose lobes are heart-shaped, a triangular upright hairy stalk, flowers growing in long bunches at the ends of the branches, and and jointed incurved pods. Hedysarum triphyllum, caule triangulari, foliis mucronatis, siliquis tenuibus intortis. Houst. Three-leaved French Honeyfuckle, with a triangular stalk, pointed leaves, and a narrow contorted pod.
12. HEDYSARUM (*Glabrum*) foliis ternatis obcordatis, caule paniculato, leguminibus monospermis glabris. French Honeyfuckle with trifoliate heart-shaped leaves, a paniculated stalk, and smooth pods containing one seed. Hedysarum triphyllum, annuum, erectum, siliquis intortis, & ad extremitatem amplioribus. Houst. Three-leaved, annual, upright French Honeyfuckle, with contorted pods, which are broad at their extremity.
13. HEDYSARUM (*Scandens*) foliis ternatis, foliolis obversè-ovatis, caule volubili, spicâ longissimâ reflexâ. Three-leaved French Honeyfuckle, with obverse oval lobes, a twining stalk, and a very long reflexed spike of flowers. Hedysarum triphyllum Americanum scandens, flore purpureo. Three-leaved, climbing, American French Honeyfuckle, with a purple flower.
14. HEDYSARUM (*Repens*) foliis ternatis obcordatis, caulibus procumbentibus racemis lateralibus. Lin. Sp. 1056. Three-leaved French Honeyfuckle, with oval heart-shaped leaves, trailing hairy stalks, and flowers on the side of the stalks. Hedysarum procumbens, trifolii fragiferi folio. Hort. Elth. 172. Trailing French Honeyfuckle, with leaves like the Strawberry Trefoil.
15. HEDYSARUM (*Maculatum*) foliis simplicibus ovatis obtusis. Hort. Cliff. 449. French Honeyfuckle, with oval, obtuse, single leaves. Hedysarum humile, caparidis folio maculato. Hort. Elth. 170. Low French Honeyfuckle, with a spotted Caper leaf.
16. HEDYSARUM (*Frutescens*) foliis ternatis ovato-lanceolatis, subtus villosis, caule frutescente villoso. Trifoliate

Trifoliate French Honeyfuckle, with oval spear-shaped leaves, hairy on their under side, and a shrubby hairy stalk. Quere, Whether this be not the Hedysarum foliis ternatis sub-ovatis subtus villosis caule frutescente. Flor. Virg. 174. Three-leaved French Honeyfuckle, with oval leaves and a shrubby stalk.

17. HEDYSARUM (*Pedunculatum*) foliis ternatis, foliolo intermedio pediculo longiore, racemis alaribus erectis longissimis. *French Honeyfuckle with trifoliate leaves, the middle lobe standing on a longer foot-stalk, and very long bunches of flowers coming from the sides of the stalks.*

18. HEDYSARUM (*Alhagi*) foliis simplicibus lanceolatis obtusis, caule fruticoso spinoso. Lin. Sp. Plant. 745. *French Honeyfuckle with single, spear-shaped, obtuse leaves, and a prickly shrubby stalk. Alhagi Maurorum. Rauwolf. 94. The Alhagi of the Moors.*

19. HEDYSARUM (*Triquetrum*) foliis simplicibus cordato-oblongis integerrimis glabris. *French Honeyfuckle with single, oblong, heart-shaped leaves, which are smooth and entire. Onobrychis Zeylanica aurantii folio. Pet. Hort. Scic. 247. Cockshoe of Ceylon with an Orange-leaf.*

20. HEDYSARUM (*Echastaphyllum*) foliis simplicibus ovatis subtus sericeis, petiolis muticis. Amoen. Acad. 5. p. 403. *French Honeyfuckle with oval single leaves, silky on their under side, and a spiked foot-stalk. Spartium scandens, citri foliis, floribus albis ad nodos confertim nascentibus. Plum. Sp. 19.*

21. HEDYSARUM (*Gangeticum*) foliis simplicibus ovatis acuminatis, spicis longissimis nudis terminalibus. *French Honeyfuckle with oval-pointed single leaves, and very long naked spikes of flowers terminating the stalks. An Hedysarum foliis simplicibus ovatis acutis basi stipulatis. Lin. Sp. 1052.*

The first sort has been long cultivated in the English gardens for ornament. This grows naturally in Italy; there are two varieties of this, one with a bright red, and the other a white flower, which very rarely vary from one to the other; but as there is no other difference but in the colour of their flowers, so they are supposed to be the same species.

It is a biennial plant, which flowers the second year, and soon after the seeds are ripe, the roots generally perish: this sends up several hollow smooth stalks two or three foot long, which branch out on each side, garnished with winged leaves, composed of five or six pair of oval lobes, terminated by an odd one; the leaves are placed alternate, and from their base comes out foot-stalks which are five or six inches long, sustaining spikes of beautiful red flowers; these are succeeded by compressed jointed pods, which are very rough, standing erect; in each of the joints is lodged one kidney-shaped seed. This sort flowers in June and July, and the seeds ripen in September. The white is only a variety of this, and as such, is sometimes preserved in gardens.

They are propagated by sowing their seeds in April, in a bed of light fresh earth; and when the plants come up, they should be transplanted into other beds of the like earth, and in an open situation, at about six or eight inches distance from each other, leaving a path between every four rows, to go between them to hoe, and clear them from weeds. In these beds they may remain until Michaelmas, then may be transplanted into the large borders of a parterre or pleasure-garden, allowing them at least three feet distance from other plants, amongst which they should be interspersed, to continue the succession of flowers; where they will make a fine appearance when blown, especially the red sort, which produces very beautiful flowers.

As these plants decay after they have perfected their seeds, so there should annually be a fresh supply of plants raised, where they are desired, for the old roots seldom continue longer. They are very proper ornaments for large borders, or to fill up vacancies among shrubs, but they grow too large for small borders, unless their stalks are pruned off, leaving only two or three on each plant; which, if kept upright

with sticks, will prevent their hanging over other flowers. They are propagated for supplying the markets with plants to adorn the London gardens and balconies, by the gardeners in the neighbourhood of London.

The second sort is an annual plant, which grows naturally in Spain and Portugal; the leaves of this are narrow and oblong, four or five pair being placed along the midrib, with an odd one at the end; the stalks are terminated by small spikes of purple flowers, which are succeeded by small rough pods, shaped like those of the former sort. This plant is preserved in botanic gardens for the sake of variety; it is propagated by seeds, which should be sown the beginning of April, in the place where the plants are to remain, and will require no other culture but to thin them where they are too near, and keep them clean from weeds. This flowers in July, and the seeds ripen in autumn.

The third sort hath a perennial root, which will abide many years if planted in a dry soil. This is propagated by sowing the seeds in the manner directed for the former; but when the plants are come up two inches high, they should be transplanted where they are to remain for good; but if they are not too thick in the seed-bed, they may be suffered to remain there until the following autumn; at which time they should be carefully taken up, and transplanted into the borders where they are designed to stand; for their roots generally run down very deep, so that it is not safe to remove them often. This plant produces its flowers about the same time of the year as the former, and if the season proves favourable, perfects its seeds in autumn; and the roots will abide in the open air very well, resisting the severest cold, provided they are planted in a dry soil.

The fourth sort is an annual plant, which grows naturally in the Levant. This hath some resemblance of the first, but is much smaller; the stalks arise near a foot high, and are garnished with winged leaves, composed of two or three pair of oval lobes, terminated by an odd one; the flowers come out in spikes at the top of the stalks, which are of a pale red intermixed, with a little blue. These appear in July, and are succeeded by jointed pods which are waved on both sides, forming an obtuse angle at each joint; the seeds ripen in the autumn. This is propagated in the same way as the second sort, and is equally hardy.

The fifth sort grows naturally in both Indies; the seeds of this were sent me from La Vera Cruz, by the late Dr. Houstoun. This is an annual plant, with a long tap root which runs deep in the ground, sending out one or two stalks, which rise about nine inches high, the lower part being garnished with oval leaves by pairs on each foot-stalk; but the upper part of the stalk where the flowers come out, is garnished with small leaves, ending in acute points, sitting close to the stalks, and at each of these is situated a single, small, yellow flower, inclosed by the two leaves. These make but little appearance, and are succeeded by oblong pods, containing one kidney-shaped seed.

The sixth sort was sent me by the late Dr. Houstoun from La Vera Cruz, where he found it growing naturally, as it also does in Jamaica. This is an annual plant, which rises with a shrubby stalk upward of four feet high, dividing into several branches, which are garnished with oblong oval leaves that are trifoliate, standing upon pretty long foot-stalks, the middle lobe standing an inch beyond the other two; the branches are terminated by long loose panicles of purple flowers, which are succeeded by narrow jointed pods which are twisted. These plants flower in July, and their seeds ripen in autumn.

The two last mentioned are tender plants, so their seeds must be sown in the spring upon a hot-bed; and when the plants are fit to remove, they should be each planted in a separate small pot, filled with light earth, and plunged into a hot-bed, keeping them shaded from the sun till they have taken new root; then

H E D

then they must be treated in the same way as other tender plants from hot countries, always keeping them in the stove or glass-case, otherwise they will not flower or produce seeds in England.

The seventh sort grows naturally in Jamaica, from whence the seeds were sent me by the late Dr. Houstoun. This is a shrubby plant, which rises about five feet high, and divides into several branches, which are garnished with trifoliate leaves which are oval, the middle lobe being much larger than the other two; the stalks are terminated by long spikes of small purple flowers, which are succeeded by narrow pods, strait on one side, but jointed on the other.

The eighth sort was sent me from La Vera Cruz by the late Dr. Houstoun, who found it growing there naturally. This rises with a shrubby stalk six or seven feet high, dividing into several branches, which are garnished with trifoliate oval leaves, silky and white on their under side, but of a pale green on their upper side; the flowers come out in long narrow spikes from the wings, and at the end of the branches, sitting close to the stalks; they are small, of a bright purple colour, and are succeeded by flat, smooth, jointed pods, about one inch long, each joint having one kidney-shaped seed.

The two last sorts will continue two or three years, if the plants are placed in the bark-stove. They are propagated by seeds, which must be sown upon a hot-bed, and the plants treated in the same manner as those just before-mentioned; and when they have obtained height, they should be removed into the bark-stove, where they should constantly remain, allowing them a large share of air in warm weather. These plants seldom flower till the second year, when they will produce seeds which ripen in the autumn.

The ninth sort is an annual plant, which grows naturally at La Vera Cruz, from whence it was sent me by the late Dr. Houstoun. This seldom rises more than eight or nine inches high, sending out several branches from the root, which are diffused and hairy; they are closely garnished with small, oval, trifoliate leaves, a little hoary. The flowers grow in close short spikes; they are purple, and have very hairy empalements.

The tenth sort grows naturally in Jamaica. This hath ligneous trailing stalks a foot and a half long, sending out several branches on each side, which are garnished with small, round, trifoliate leaves, of a pale green colour; the flowers are produced in very loose spikes at the ends of the branches; they are small, and of a pale purplish colour, succeeded by narrow twisted pods which are jointed, each joint being four cornered, containing a single, small, compressed seed.

The two last sorts being annual, require the same treatment as the fifth and sixth sorts before-mentioned, with which management they will flower and ripen their seeds in this country.

The eleventh sort is a shrubby plant, which rises with triangular stalks five or six feet high, dividing into several branches, garnished with heart-shaped trifoliate leaves, ending in acute points; the flowers are produced in very long spikes at the end of the branches, which are of a pale purple colour, and are succeeded by narrow jointed pods which are variously twisted; the seeds are small and compressed.

This plant grows naturally in Jamaica, from whence the seeds were sent me by the late Dr. Houstoun. It will continue three or four years, if the plants are treated in the same manner directed for the seventh and eighth sorts, and will perfect seeds in this country.

The twelfth sort is annual, the seeds of it were sent me by the late Dr. Houstoun from Campeachy. This hath a paniculated stalk, which rises about two feet high, garnished with heart-shaped trifoliate leaves; the upper part of the stalk branches out into panicles of flowers, which are of a pale purple colour; these are succeeded by lunulated compressed pods, which stand oblique to the stalk, each containing one com-

H E D

pressed kidney-shaped seed. This sort is propagated by seeds, and requires the same treatment as the fifth and sixth sorts.

The thirteenth sort was sent me from La Vera Cruz, by the late Dr. Houstoun. This hath a twining stalk, which gets round the trees and shrubs which grow near it, and climbs to the height of ten or twelve feet, garnished with obverse, oval, trifoliate leaves, standing upon pretty long foot-stalks; the flowers are produced in very long spikes, which are reflexed; they are of a dark purple colour, and sit close to the stalk. This is an abiding plant, which requires a stove to preserve it in this country, so the plants should be treated in the same manner as the seventh and eighth sorts.

The fourteenth sort is an annual plant, which grows naturally in both Indies. The seeds of this were sent me from the Havannah by the late Dr. Houstoun; it hath trailing branches near a foot long, which are garnished with round trifoliate leaves, a little indented at the top, very like in shape to those of the Strawberry Trefoil; the stalks and under side of the leaves are hairy; the flowers are produced toward the end of the branches, sometimes single, and at other times two at a joint; they are of a purple colour and small; these are succeeded by pods about an inch long, which are strait on one side, and jointed on the other. This flowers the end of July, and sometimes perfects seeds here.

The fifteenth sort is a low annual plant, having slender stalks near a foot long, their lower part being garnished with single oval leaves, standing upon slender foot-stalks; their upper part is adorned with flowers, which come out by pairs above each other, to the end of the stalk; they are but small, and of a reddish yellow colour; these are succeeded by jointed narrow pods, which sit close to the stalk, and are sickle-shaped. The two last mentioned are annual plants, which require the same culture as the fifth and sixth sorts.

The sixteenth sort was sent me by the late Dr. Dale, from South Carolina. This hath a perennial root, from which arise two or three shrubby hairy stalks near two feet high, branching out on every side near the top, garnished with oval, spear-shaped, trifoliate leaves, which are hairy on their under side, and stand upon short foot-stalks; the flowers are produced at the end of the branches in short spikes; they are of a purplish yellow colour, and small; the stalks of this sort decay every autumn, and new ones arise in the spring. It is propagated by seeds, which should be sown upon a hot-bed in the spring, and when the plants are fit to remove, they should be planted in separate small pots filled with light earth, and plunged into a moderate hot-bed, observing to shade them until they have taken new root; then they should have a large share of air admitted to them in warm weather, and in summer they may be exposed to the open air, but in the autumn they must be placed under a frame to screen them from frost; the following spring some of these plants must be shaken out of the pots and planted in a warm border, where, if the summer proves warm, they will flower, but these seldom perfect their seeds; therefore two or three plants should be put into larger pots, and plunged into a moderate hot-bed, which will bring them early into flower; so that if the glasses are kept over them in bad weather, these will ripen their seeds in autumn, and the roots will continue some years, if they are screened from frost in winter.

The seventeenth sort was sent me with the last, by the same gentleman, from South Carolina. This hath a perennial root and an annual stalk, which grows erect about two feet high, garnished with long trifoliate leaves, which are rounded at their base where they are broadest, and narrowed all the way to a point; they are near three inches and a half long, and half an inch broad at their base; of a light green colour, and smooth; the two side lobes sit pretty close to the stalk, but the middle

H E D

middle one sits upon a foot-stalk an inch long; the flowers are produced in long spikes from the wings of the stalk, growing erect; the lower part of the spike is but thinly set with flowers, but on the upper part they are disposed very close; these are small, and of a bright yellow colour, sitting very close to the stalks, and are succeeded by jointed pods strait on one side.

This plant is propagated by seeds, and requires the same treatment as the last mentioned, with which it will flower and produce ripe seeds.

The eighteenth sort grows naturally in Syria, where it is one of the beauties of the country. It rises with shrubby stalks about three feet high, which branch out on every side, and are garnished with single leaves, shaped like those of the broad-leaved Knot-grass; they are very smooth, of a pale green colour, and stand on short foot-stalks; under these leaves come out thorns, which are near an inch long, of a reddish brown colour; the flowers come out from the side of the branches in small clusters; they are of a purple colour in the middle, and reddish about the rims; these are succeeded by pods, which are strait on one side, and jointed on the other, bending a little in shape of a sickle. This plant is at present pretty rare in the English gardens; it is propagated by seeds, which will frequently lie a year in the ground before they vegetate, therefore should be sown in pots filled with light earth, and plunged into a moderate hot-bed; and if the plants do not appear by the beginning of June, the pots should be taken out of the bed, and placed where they may have only the morning sun, keeping them clean from weeds; and in the autumn, they should be plunged into an old bed of tanners bark under a frame, where they may be screened from the frost and hard rains in the winter, and in spring plunged into a fresh hot-bed, which will bring up the plants: when these are fit to remove, they should be each planted into a separate small pot, filled with light earth, and plunged into a very moderate hot-bed, shading them from the sun till they have taken new root; then they should be gradually hardened to bear the open air, into which they should be removed in June, placing them in a sheltered situation, where they may remain till the autumn; when, if they are plunged into an old tan-bed under a frame, where, in mild weather they may enjoy the free air, and be protected from frost, they will succeed better than if placed in a greenhouse, or more tenderly treated. I have seen this plant growing in the full ground, in a very warm border, where, by covering it in frosty weather, it had endured two winters, but a severe frost happening the third winter entirely killed it.

From this shrub the Persian Manna is collected, which is an exudation of the nutritious juice of the plant. This drug is chiefly gathered about Tauris, a town in Persia, where the shrub grows plentifully. Sir George Wheeler found it growing in Tinos, and supposed it was an undescribed plant. Tournefort found it in plenty in many of the plains in Armenia and Georgia, and made a particular genus of it under the title of *Alhagi*.

The nineteenth sort grows naturally in India, from whence the seeds have been lately brought to Europe, and several plants have been raised in the English gardens; these have leaves so like those of the Orange-tree, as scarcely to be distinguished while young; but as there are not any plants here of a large size, so I can give no further account of this sort at present.

The twentieth sort was sent me from Carthage in New Spain, by the late Dr. Floufoun: this is a perennial plant with a twining stalk, which twists round any neighbouring support, rising to the height of ten or twelve feet, sending out a few small branches from the side, garnished with oval leaves four or five inches long, and an inch and a half broad in the middle; the under side of the leaves are like satin; the flowers are white, coming out from the side of the stalk in close bunches; they are of the same form with the other species of this genus, and are succeeded by short pods, containing one or two kidney-shaped seeds.

The seeds of the twenty-first sort I received from the

H E L

East-Indies; this is an annual plant, which rises about three feet high, having a slender stalk inclining to be shrubby, garnished with oval leaves placed single on very short foot-stalks; some of the plants send out one or two slender branches from the main stalk, the lower part of which are garnished with leaves of the same form with those on the principal stalk, but are smaller: the upper part of the principal stalk and the branches are garnished with flowers near a foot in length, which are of a worn-out purple colour, standing single at each joint: these are succeeded by jointed pods an inch and a half long, containing three or four kidney-shaped seeds in each.

These two sorts are too tender to thrive in the open air in England; they are both propagated by seeds, which must be sown on a hot-bed early in the spring; and when the plants are come up, and fit to remove, they should be parted, and each planted in a separate small pot, plunging them into a fresh hot-bed, where they should be screened from the sun till they have taken new root; after which, they should be treated in the same manner as other tender plants. The twenty-first sort must be placed in the bark-stove in autumn, but the other will ripen seeds the same year the beginning of October.

HEDYSARUM *Zeylanicum majus & minus*. See *ÆSCHYNOMENE*.

HEDYSARUM *mimosæ foliis*. See *ÆSCHYNOMENE*.

HELENIUM. Lin. Gen. Plant. 863. *Heleniastrum*. Vaill. Act. R. Par. 1720. Bastard Sun-flower.

The CHARACTERS are,

It hath a flower composed of several hermaphrodite florets, which form the disk, and female half florets which compose the rays. The hermaphrodite florets are tubulous, and cut into five parts at the brim; these have each five short hairy stamens, terminated by cylindrical summits, with an oblong germen supporting a slender style, crowned by a bifid stigma. The germen afterward becomes an angular single seed, crowned by a small five-pointed empalement. The female florets in the border have short tubes, and are stretched out on one side like a tongue to form the ray; these are cut into five segments at their points, where they are broad. The female flowers have no stamens, but have an oblong germen, which turns to a single seed like those of the hermaphrodite flowers; these are all included in one common single empalement, which spreads open, and is cut into several segments.

This genus of plants is ranged in the second section of Linnaeus's nineteenth class, which includes those plants which have compound flowers, the hermaphrodite florets in the center, and the female half florets on the border, being both fruitful.

The SPECIES are,

1. **HELENIUM** (*Autumnale*) *foliis lanceolatis-linearibus integerrimis glabris, pedunculis nudis unifloris. Helenium with spear-shaped narrow leaves, which are smooth, entire, and naked foot-stalks with single flowers. Heleniastrum folio longiore & angustiore*. Vaill. Act. R. Par. 1720. Bastard Sun-flower with a longer and narrower leaf.

2. **HELENIUM** (*Latifolium*) *foliis lanceolatis acutis serratis, pedunculis brevioribus, calycibus multifidis. Helenium with pointed, spear-shaped, sawed leaves, shorter foot-stalks, and a many-pointed empalement. Heleniastrum folio brevioris & latiore*. Vaill. Act. R. S. 1720. Bastard Sun-flower with a broader and shorter leaf.

These plants rise to the height of six or seven feet in good ground; the roots, when large, send up a great number of stalks, which branch toward the top; those of the first sort are garnished with smooth leaves, which are three inches and a half long, and half an inch broad in the middle, with entire edges sitting close to the stalks, and from their base is extended a leafy border along the stalk, so as to form what was generally termed a winged stalk, but Linnaeus calls it a running leaf; the upper part of the stalk divides, and from each division arises a naked foot-stalk about three inches long, sustaining one yellow flower at the top, shaped like a Sun-flower, but much smaller, having long rays, which are jagged pretty

deep into four or five segments; these appear in August, and there is a succession of flowers on the plants till the frost puts a stop to them.

The second sort hath the appearance of the first, but the leaves are not three inches long, and are more than an inch broad in the middle, ending in acute points, and are sharply sawed on their edges. The flowers stand upon shorter foot-stalks, growing closer together; for the stalks of this do not branch near so much as those of the other; they both flower at the same season.

There is also another sort with leaves as narrow as the first, which are acutely indented on the edges. The stalks branch at the top somewhat like those of the first, but the middle flowers have much shorter foot-stalks than those which branch on the side, and are garnished with small leaves, almost to the top; but I am not certain if this is a distinct species, or only a variety which has accidentally risen from the seeds of the other.

These plants are both of them natives of America; the seeds of both sorts I have received from Virginia and New England, where they grow wild in great plenty in the woods, and other shady places where the ground is moist. They may be propagated by seeds, or by parting their roots; but the latter is generally practised in this country, because they seldom perfect their seeds here; but if the seeds are procured from abroad, they should be sown the beginning of March on a border of light earth; and if the seeds should not come up the first year, the ground should not be disturbed, because they often remain a whole year in the ground before the plants come up; in which case there is nothing more to be done, but to keep the ground clear from weeds, and wait until the plants rise. When they appear, if the season proves dry, they must be often watered, which will greatly forward their growth; and where the plants come up too close to each other, they should be thinned, and transplanted out into beds a foot asunder every way, being careful to shade them until they have taken root, as also to water them in dry weather. In autumn they may be transplanted where they are to remain, and the following summer they will produce their flowers, which will continue till the frost prevents them; and their roots will abide many years, and afford many offsets, by which they may be increased.

The best season to transplant the old roots, and to part them for increase, is in the end of October, when their flowers are past, or the beginning of March, just before they begin to shoot; but if the spring should prove dry, they must be duly watered, otherwise they will not produce many flowers the same year; these plants should not be removed oftener than every other year, if they are expected to flower strong; they delight in a soil rather moist than dry, provided it be not too strong, or holds the wet in winter; but if they are planted in a dry soil, they must be often and plentifully watered in dry weather, to make them produce plenty of flowers.

HELENIUM, Elecampane. See INULA.

HELIANTHEMUM. Tourn. Inst. R. H. 248. tab. 128. Cistus. Lin. Gen. Plant. 598. Dwarf Cistus; or Sun-flower.

The CHARACTERS are,

The flower has a three-leaved empalement, which is permanent, which afterward covers the seed-vessel. It hath five roundish petals which spread open, with a great number of erect stamina, which are terminated by small roundish summits. In the center is situated an oval germen, supporting a single style the length of the stamina, crowned by an obtuse stigma. The germen afterward becomes a roundish, or oval capsule, with three cells, opening in three parts, filled with small roundish seeds.

This genus of plants is joined by Dr. Linnæus to that of Cistus, and is ranged in the first section of his thirteenth class, which includes those plants whose flowers have many stamina and one style. As the empalement of the flower has but three leaves, and

those of Cistus five, and the capsule of the Helianthemum has but three cells, and that of Cistus five, so these characters are sufficient to admit of their being separated into different genera; and as there are a great number of species of both sorts, so by this separation they may be better ascertained.

The SPECIES are,

1. HELIANTHEMUM (*Chamaecistus*) caulibus procumbentibus suffruticosis, foliis oblongis subpilosis, stipulis lanceolatis. Dwarf Cistus with trailing shrubby stalks, oblong hairy leaves, and spear-shaped stipule. Helianthemum vulgare flore luteo. J. B. 2. 15. Common Dwarf Cistus with a yellow flower.
2. HELIANTHEMUM (*Germanicum*) caulibus procumbentibus suffruticosis, ramosissimis, spicis florum longioribus. Dwarf Cistus with trailing shrubby stalks full of branches, and longer spikes to the flowers. Helianthemum album Germanicum. Tab. Icon. 1062. White German Dwarf Cistus.
3. HELIANTHEMUM (*Pileus*) caulibus suffruticosis pilosis foliis lanceolatis obtusis, spicis reflexis. Dwarf Cistus with hairy shrubby stalks, blunt spear-shaped leaves, and reflexed spikes of flowers. Helianthemum foliis majoribus, flore albo. J. B. 2. 16. Dwarf Cistus with larger leaves and a white flower.
4. HELIANTHEMUM (*Apenninum*) incanum, caulibus suffruticosis erectis, foliis lanceolatis hirsutis. Hoary Dwarf Cistus with erect shrubby stalks, and hairy spear-shaped leaves. Helianthemum saxatile, foliis & caulibus incanis, floribus albis, Appenini montis. Mentz. Pug. tab. 8. Rock Dwarf Cistus of the Apennines, with hoary stalks and leaves, and white flowers.
5. HELIANTHEMUM (*Umbellatum*) caule procumbente non ramoso, foliis linearibus incanis oppositis. Dwarf Cistus with an unbranched trailing stalk, and narrow hoary leaves placed opposite. Helianthemum folio thymi incano. J. B. 2. 19. Dwarf Cistus with a hairy Thyme leaf.
6. HELIANTHEMUM (*Fumana*) caule suffruticoso procumbente, foliis linearibus alternis, floribus auriculatis. Dwarf Cistus with a shrubby trailing stalk, very narrow leaves placed alternate, and auriculated flowers. Helianthemum tenuifolium glabrum luteo flore, per humum sparsum. J. B. 2. 18. Smooth narrow-leaved Dwarf Cistus, with a yellow flower and trailing stalks.
7. HELIANTHEMUM (*Sempuchifolium*) caule suffruticoso procumbente, foliis lanceolatis oppositis, pedunculis longioribus, calycibus hirsutis. Dwarf Cistus with a shrubby trailing stalk, spear-shaped leaves placed opposite, longer foot-stalks to the flowers, and hairy empalements. Helianthemum sive Cistus humilis, folio sempuchi, capitulis valde hirsutis. J. B. 2. 20. Dwarf Cistus with a Marjoram leaf, and very hairy heads.
8. HELIANTHEMUM (*Serpillifolium*) caule suffruticoso procumbente, foliis linearibus oppositis, floribus umbellatis. Dwarf Cistus with a shrubby trailing stalk, very narrow leaves placed opposite, and flowers growing in an umbel. Helianthemum folio thymi floribus umbellatis. Tourn. Inst. 250. Dwarf Cistus with a Thyme leaf and umbellated flowers.
9. HELIANTHEMUM (*Cistifolium*) caulibus procumbentibus suffruticosis glabris, foliis ovato lanceolatis oppositis, pedunculis longioribus. Dwarf Cistus with shrubby trailing stalks which are smooth, oval spear-shaped leaves placed opposite, and longer foot-stalks to the flowers. Helianthemum Germanicum luteum Cisti folio. Boëth. Yellow German Dwarf Cistus with a Rock Rose leaf.
10. HELIANTHEMUM (*Tuberaria*) caule lignoso perenne, foliis radicalibus ovatis trinerviis tomentosis caulinis glabris lanceolatis alternis. Perennial Dwarf Cistus with a woody stalk, whose lower leaves are oval, woolly, with three veins, those on the stalks smooth, spear-shaped, and placed alternate. Helianthemum plantaginis folio perenne. Tourn. Inst. 250. Perennial Dwarf Cistus with a Plantain leaf.
11. HELIANTHEMUM (*Polidifolium*) caulibus sessilibus suffruticosis, foliis lanceolatis oppositis tomentosis caule florali racemoso. Dwarf Cistus with very short shrubby stalks, woolly spear-shaped leaves placed opposite, and a branching

- branching flower-stalk.* Helianthemum foliis polii montani. Tourn. Inst. 249. Dwarf Cistus with leaves like Poley Mountain.
12. HELIANTHEMUM (Nummularium) caule suffruticoso procumbente, foliis ovatis nervosis, subtus incanis. Dwarf Cistus with a shrubby trailing stalk, and oval veined leaves, white on their under side. Helianthemum ad nummulariam accedens. J. B. 2. 20. Dwarf Cistus resembling Moneywort.
13. HELIANTHEMUM (Lavendulæfolium) caule suffruticoso, foliis lineari-lanceolatis oppositis subtus tomentosis. Dwarf Cistus with a shrubby stalk, and narrow spear-shaped leaves placed opposite, which are woolly on their under side. Helianthemum lavendulæ folio. Tourn. Inst. 249. Dwarf Cistus with a Lavender leaf.
14. HELIANTHEMUM (Hirtum) caule suffruticoso erecto, foliis linearibus margines revolutis subtus incanis. Dwarf Cistus with a shrubby erect stalk, and narrow leaves reflexed on their edges, with their under side hoary. Helianthemum foliis Rorismarini splendentibus, subtus incanis. Tourn. Inst. 250. Dwarf Cistus with shining Rosemary leaves, which are hoary on their under side.
15. HELIANTHEMUM (Surrejanum) caulibus suffruticosis procumbentibus, foliis oblongo-ovatis subhirsutis, petalis acuminatis reflexis. Dwarf Cistus with trailing shrubby stalks, oblong oval hairy leaves, and acute-pointed reflexed petals to the flowers. Helianthemum vulgare petalis florum perangustis. Hort. Elth. 177. tab. 145. Common Dwarf Cistus with narrow petals to the flowers.
16. HELIANTHEMUM (Lusitanicum) caule suffruticoso erecto, foliis lanceolatis incanis glabris caule florali ramoso. Dwarf Cistus with a shrubby upright stalk, hoary spear-shaped leaves, which are smooth, and branching flower-stalks. Helianthemum Lusitanicum, mari folio incano, flore luteo. Tourn. Inst. 250. Portugal Dwarf Cistus with a hoary Marum leaf, and a yellow flower.
17. HELIANTHEMUM (Roseum) caule suffruticoso, foliis oblongo-ovatis oppositis, summis linearibus alternis. Dwarf Cistus with a shrubby stalk, oblong oval leaves placed opposite, those toward the top being narrow and alternate. Helianthemum ampliore folio, flore roseo. Sherard. Act. Phil. N°. 383. Dwarf Cistus with a larger leaf, and Rose-coloured flower.
18. HELIANTHEMUM (Guttatum) caule herbaceo hirsuto, foliis lanceolato-linearibus pilosis, pedunculis longioribus. Dwarf Cistus with an herbaceous stalk which is hairy, narrow spear-shaped hairy leaves, and longer foot-stalks to the flowers. Helianthemum flore maculoso. Col. Ceph. 2. p. 78. Dwarf Cistus with a spotted flower.
19. HELIANTHEMUM (Fugacium) caule herbaceo, foliis subovatis pilosis, flore fugaci. Dwarf Cistus with an herbaceous stalk, hairy oval leaves, and a fugacious flower. Helianthemum annuum humile, foliis subovatis, flore fugaci. Allion. Annual Dwarf Cistus with oval leaves, and a fugacious flower.
20. HELIANTHEMUM (Ledifolium) caule herbaceo erecto, foliis lanceolatis oppositis, floribus solitariis, capsulis maximis. Dwarf Cistus with an erect herbaceous stalk, spear-shaped leaves placed opposite, flowers growing singly, and very large capsules. Helianthemum Ledi folio. Tourn. Inst. 249. Dwarf Cistus with a Ledon leaf.
21. HELIANTHEMUM (Salicifolium) caule herbaceo ramoso, foliis oblongo-ovatis oppositis, summis alternis, floribus solitariis. Dwarf Cistus with a branching herbaceous stalk, oblong oval leaves placed opposite, those toward the top growing alternate, and solitary flowers. Helianthemum salicis folio. Tourn. Inst. 249. Dwarf Cistus with a Willow leaf.
22. HELIANTHEMUM (Fasciculatum) foliis fasciculatis. Royen. Dwarf Cistus with leaves growing in bunches.
23. HELIANTHEMUM (Ægyptiacum) herbaceum erectum, foliis lineari-lanceolatis petiolatis, calycibus inflatis corolla majoribus. Dwarf Cistus with erect herbaceous stalks, linear spear-shaped leaves, and swelling empalements larger than the petals.

24. HELIANTHEMUM (Marifolium) caule herbaceo procumbente, foliis ovatis tomentosis sessilibus. Dwarf Cistus with an herbaceous trailing stalk, and oval woolly leaves sitting close to the branches. Helianthemum Alpinum, folio pilosellæ minoris Fuchsi. J. B. 2. 18. Hoary Dwarf Cistus of the Alps, with lesser Cat's-foot leaves.

The first sort grows naturally on the chalky hills and banks in many parts of England; the stalks of this plant are ligneous and slender, trailing upon the ground, extending themselves near a foot each way; these are garnished with small oblong leaves, of a dark green on their upper side, but of a grayish colour on their under. The flowers are produced at the end of the stalks in loose spikes; they are composed of five deep yellow petals, which spread open in the day, but shut close in the evening; these appear in June and July, and are succeeded by roundish capsules, inclosing many angular seeds, which ripen in August and September, and the roots last several years.

The second sort grows naturally in Germany; the stalks of this are much larger, and extend farther than those of the first; the leaves are longer, and are hoary; there are three acuminate stipula at each of the lower joints, which are erect. The spikes of flowers are much longer than those of the former, and the flowers are white and larger. The empalement of the flowers are hairy and whitish; these differences are lasting from seeds.

The third sort grows naturally in the south of France, in Italy, and Germany. The stalks of this grow more erect than either of the former, and are more ligneous. The joints are farther asunder; the leaves are longer and hairy; the spikes of flowers are generally reflexed; they are white, and the size of those of the second; the stipula of this are very narrow.

The fourth sort grows naturally on the Apennine mountains; the stalks of this are more erect than those of the third. The leaves are not so long, the stipula are very small, and the whole plant is very hoary. The flowers are white, and the spikes are shorter and more compact than either of the former.

The fifth sort grows naturally in the south of France, in Spain, and Istria, from the last country I have received the seeds; this hath low trailing stalks, which are ligneous, but seldom branch, and are not more than four or five inches long. The leaves are narrow and hoary, and have no stipula at their base. The flowers are white, and are in small clusters at the end of the stalks; this sort seldom continues longer than two years.

The sixth sort hath trailing shrubby stalks, which extend a foot in length, and are garnished with very narrow smooth leaves placed alternate; but those short stalks near the root, which do not flower, have shorter and finer leaves growing in clusters; these have no stipula at their base. The flowers are placed thinly toward the end of the branches, they are yellow and auriculated; this sort grows in the south of France and Italy.

The seventh sort hath very long, trailing, ligneous stalks, which are garnished with spear-shaped leaves placed opposite, which are very hairy, and gray on their under side, having at their base three long narrow stipula. The spikes of flowers are near a foot in length, but grow thinly; they are large, and of a deep yellow colour, with very hairy empalements; this grows naturally in the south of France and Spain.

The eighth sort hath very shrubby crooked stalks, covered with a purplish brown bark like the common heath. The branches are slender, and garnished with narrow stiff leaves like those of Thyme, which stand opposite, having no stipula at their base. The flowers are produced on naked foot-stalks, which terminate the branches in a sort of umbel; they are of a pale yellow colour, and a little smaller than those of the common sort; this grows naturally on the sands near Fontainebleau, in France.

HEL

The ninth fort grows naturally in Germany, from whence the seeds were sent to the late Dr. Boerhaave, in whose curious garden near Leyden I gathered the seeds; this sends out from a ligneous root a great number of trailing stalks, which are smooth, and extend more than a foot each way, garnished with oval, spear-shaped, smooth leaves, placed opposite, having at their base three spear-shaped stipula. The flowers are large, yellow, and grow in short clusters at the end of the branches; this always continues the same from seeds.

The tenth fort grows naturally in Spain, from whence I received it; this hath a short, thick, woody stalk, from which come out several short side-branches, which are garnished with oval woolly leaves, having three longitudinal veins. The flower-stalk which arises from the main stem grows about nine inches high, having two or three narrow leaves placed alternate. The flowers are produced in pretty long pedicels toward the top of the stalk, and have very smooth empalements.

The eleventh fort was sent me from Verona, where it grows naturally; this hath a low shrubby stalk, from which come out a few short branches, garnished with small woolly spear-shaped leaves, placed opposite. The flower-stalk rises about six inches high, and branches toward the top, where the flowers are produced on pretty long foot-stalks; they are white, and smaller than those of the common fort.

The twelfth fort hath long shrubby stalks which trail on the ground, and divide into many branches, which are garnished with oval veined leaves of a light green on their upper side, but of a grayish colour below, with three narrow erect stipula at their base. The flowers are pretty large, white, and grow in clusters at the end of the branches.

The thirteenth fort hath shrubby stalks which grow pretty upright, garnished with narrow spear-shaped leaves, placed opposite, woolly on their under side, with three very narrow stipula growing at their base. The flowers are white, growing in long spikes at the end of the branches; this grows naturally in the south of France.

The fourteenth fort hath an erect shrubby stalk, which sends out many side branches, whose joints are pretty close, and are garnished with very narrow leaves, placed opposite, whose borders are reflexed; their upper side is of a lucid green, and their under side hoary. The flowers are pretty large, white, and grow in small clusters at the end of the branches; this grows naturally in Spain, from whence the roots were sent me.

The fifteenth fort was found by Mr. Edmund Du Bois, near Croydon, in Surry, and was at first supposed to be only an accidental variety of the common fort, but the seeds of this always produce the same. I have cultivated this above thirty years, and never have found it vary from seeds; this is very like the common fort, but the leaves are hairy. The petals of the flowers are star-pointed, and smaller than those of the common fort.

The sixteenth fort hath upright shrubby stalks, which rise a foot and a half high, sending out branches the whole length; these are garnished with small spear-shaped silvery leaves, placed opposite, which are smooth. The flower-stalks branch, and the flowers, which are white, are produced in short spikes at the end of the branches.

The seventeenth fort was found growing naturally by the late Dr. William Sherrard, near Smyrna, who sent the seeds to England; this hath shrubby stalks which do not trail on the ground, garnished with oblong oval leaves placed opposite, but those toward the top are narrow and placed alternate. The flowers are produced at the end of the branches in long loose spikes; they are of a Rose colour, and the size of those of the common fort.

The eighteenth fort is annual; this grows naturally in France, Spain, Italy, and in Jersey, where the late Dr. William Sherrard found it, and sent the seeds to

HEL

England; this hath a branching herbaceous stalk, which rises four or five inches high, garnished with narrow spear-shaped leaves, placed opposite, which are covered with hairs; those on the upper part of the stalks are placed alternate, and are narrower. The flowers are produced in loose spikes at the end of the branches, standing upon long foot-stalks; they are small, and composed of five yellow petals, with a dark purple spot at the base of each; these flowers are very fugacious, for they open early in the morning, and their petals drop off in a few hours after, so that by ten of the clock the flowers are all fallen.

The nineteenth fort grows naturally upon Mount Baldus, from whence the seeds were sent me; this is an annual plant, which sends out many herbaceous stalks from the root, garnished with oval leaves, which are hairy. The flowers are produced in loose spikes at the end of the branches; they are of a pale yellow colour, and very fugacious, seldom lasting two hours before the petals fall off: there is another variety of this which grows about Verona, with upright stalks.

The twentieth fort grows naturally in the south of France and Italy, and was found by the late Dr. William Sherrard, growing near Smyrna, who sent the seeds to England and Holland by a new title, supposing it to be a different plant; but when it was cultivated here, it proved to be the same with that growing in the south of France; for this plant puts on different appearances, according to the soil and situation where it grows; for, in a good soil, where the plants stand single, and are not injured by weeds, they will rise near a foot and a half high, the leaves will be two inches and a half long, and near half an inch broad in the middle; but in a poor soil, or where the plants stand too close, or are injured by weeds or neighbouring plants, they do not rise more than half that height. The leaves are much narrower, and the seed-vessels not half so large; so that any person finding these plants in two different situations may be deceived, and take them for different species; but when they are cultivated in a garden in the same soil and situation, they do not differ in any particular. This is an annual plant, which perishes soon after the seeds are ripe.

The twenty-first fort is an annual plant, which grows naturally in Spain and Portugal; this hath branching stalks, which rise a foot high, garnished with oval oblong leaves placed opposite on the lower part of the stalk; but on the upper part they are alternate and narrow, a single leaf being placed between each flower, which occasions the title of Solitary Flowers, for they grow in loose spikes at the end of the branches, in the same manner as the other species.

The twenty-second fort was sent me by Dr. Adrian Van Royen, who received the seeds from the Cape of Good Hope. This rises with a shrubby stalk about nine inches high, garnished with very narrow fine leaves, growing in clusters; the flowers come out from the side and at the end of the branches, standing upon slender foot-stalks; they are of a pale Straw colour, and very fugacious, seldom continuing longer than two hours before the petals fall off. This seldom continues longer than two years.

The twenty-third fort grows naturally in Egypt; this is an annual plant having shrubby erect stalks, garnished with narrow spear-shaped leaves, standing on foot-stalks; the upper part of the stalks are adorned with white flowers, whose petals are not so large as the empalement, and being very fugacious they make but little appearance: it flowers in July, and the seeds ripen in September, soon after which the plants decay.

The twenty-fourth fort grows naturally about Kendal in Westmoreland, and in some parts of Lancashire, upon rocky situations. This hath trailing herbaceous stalks, which seldom extend more than three or four inches, garnished with oval leaves, which are very woolly, and sit close to the branches; the flowers are produced at the upper part of the branches; they are white and small, so make no great appearance.

Most of the perennial sorts of Dwarf Cistus are hardy, so will thrive in the open air in England; they are propagated by seeds, which may be sown in places where the plants are to remain, and will require no other care but to keep them clean from weeds, and thin them where they are too close, always observing to leave those sorts at a farther distance, whose stalks trail on the ground, and grow to the greatest length. These plants will continue several years, especially in a poor dry soil; but in rich ground or moist situations, they seldom last long: but as they ripen seeds in plenty, so they may be easily repaired. They all flower about the same time as the common sort, and their seeds ripen in the autumn.

The annual sorts may be propagated with as great facility; for if their seeds are sown upon a bed of common earth in April, the plants will come up in May, and require no other culture, but to thin them where they are too close, and keep them clear from weeds. These will flower in July, and the seeds ripen in the autumn. The twenty-second sort will thrive in the full ground in the same manner as the other; but unless the summer proves favourable, the seeds will not ripen: the roots have stood through the winter when the season has proved mild, without any shelter, and have flowered the following summer.

The twenty-fourth sort requires a shady situation, otherwise it will not thrive here.

HELIANTHUS. Lin. Gen. Plant. 877. Corona solis. Tourn. Inst. R. H. 489. tab. 279. [of "Heli", the sun, and "Anthos", a flower,] i. e. Sun-flower; in French, *Soliel*.

This genus of plants was titled *Corona solis*, by most of the botanic writers; but this being a compound name, Dr. Linnæus has altered it to this of *Helianthus*: it has also by some been titled *Heliotropium*, which name is now applied to another genus of plants, very different from this.

The CHARACTERS are,

It hath a compound radiated flower, the border or rays being composed of female half-florets, which are barren, and the disk of hermaphrodite florets, which are fruitful: these are contained in one common scaly empalement, whose scales are broad at their base, pointed at their ends, and expand. The hermaphrodite florets are cylindrical, swelling at their base, cut at the brim into five acute segments, which spread open; these have five stamina which are curved at bottom, as long as the tube, and terminated by tubulous summits. The germen, which is situated at the bottom of the tube, supports a slender style the length of the tube, crowned by a reflexed stigma, divided in two parts; the germen afterward becomes an oblong, blunt, four-cornered seed. The female half florets, which compose the border, are stretched out on one side like a tongue, which is long and entire; these have a germen in the bottom, but no style or stamina, and are not fruitful.

This genus of plants is ranged in the third section of Linnæus's nineteenth class, in which he includes those plants whose flowers are composed of hermaphrodite fruitful flowers in the center, and female barren flowers in the circumference.

The SPECIES are,

1. **HELIANTHUS** (*Annuus*) foliis omnibus cordatis trinerviatis, floribus cernuis. Lin. Sp. Plant. 1276. Sun-flower, whose leaves are all heart-shaped, with three veins and a nodding flower. Corona solis. Tabern. Icon. 763. and the *Helenium Indicum maximum*. C. B. P. 276. Greatest Indian Sun-flower, commonly called annual Sun-flower.
2. **HELIANTHUS** (*Multifloris*) foliis inferioribus cordatis trinerviatis, superioribus ovatis. Lin. Sp. Plant. 1277. Sun-flower whose under leaves are heart-shaped, with three veins, and the upper leaves oval. Corona solis minor scæmina. Tabern. Icon. 764. Lesser female Sun-flower, commonly called perennial Sun-flower.
3. **HELIANTHUS** (*Tuberosus*) foliis ovato-cordatis triplinerviis. Lin. Sp. Plant. 1277. Sun-flower with oval heart-shaped leaves with three nerves. Corona solis parvo flore tuberosâ radice. Tourn. Inst. 489. Sun-

flower with a small flower and a tuberous root, commonly called *Jerusalem Artichoke*; in French, *Taupinambours*.

4. **HELIANTHUS**. (*Strumosus*) radice fusli formi. Hort. Cliff. 420. Sun-flower with a spindle-shaped root. Corona solis latifolia altissima. Tourn. Inst. 489. Tallest broad-leaved Sun-flower.
5. **HELIANTHUS** (*Giganteus*) foliis alternis lanceolatis scabris, basi ciliatis, caule stricto scabro. Lin. Sp. Plant. 1278. Sun-flower with spear-shaped leaves, and a slender rough stalk. Chrysanthemum Virginianum altissimum angustifolium puniceis caulibus. Mor. Hist. 3. p. 24. Tallest Virginia Chrysanthemum, with a narrow leaf and purple stalks.
6. **HELIANTHUS** (*Divaricatus*) foliis oppositis sessilibus ovato oblongis trinerviis, paniculâ dichotomâ. Lin. Sp. Plant. 1279. Sun-flower with oblong, opposite, oval leaves, having three veins sitting close to the stalk, and a forked panicle. Chrysanthemum Virginianum repens, foliis asperis binatim sessilibus acuminatis. Mor. Hist. 3. p. 22. Creeping Virginia Chrysanthemum, with rough-pointed leaves, sitting close by pairs.
7. **HELIANTHUS** (*Trachelifolius*) foliis lanceolatis oppositis, supernè scabris, infernè trinerviis, caule dichotomo ramoso. Sun-flower with spear-shaped leaves placed opposite, whose upper surface is rough, the under having three veins and a divided stalk. Corona solis trachelii folio, radice repente. Tourn. Inst. 490. Sun-flower with a Throatwort leaf, and a creeping root.
8. **HELIANTHUS** (*Ramosissimus*) caule ramosissimo, foliis lanceolatis scabris, inferioribus oppositis, summis alternis petiolatis, calycibus foliosis. Sun-flower with a very branching stalk, rough spear-shaped leaves placed opposite at bottom, but alternate toward the top, having foot-stalks, and leafy empalements. Corona solis trachelii folio tenuiore, calycè floris foliato. Act. Phil. N° 412. Sun-flower with a narrow Throatwort leaf, and a leafy flower-cup.
9. **HELIANTHUS** (*Atrorubens*) foliis ovatis crenatis trinerviis scabris, squamis calycinis erectis longitudine disci Flor. Virg. 103. Sun-flower with oval, rough, crenated leaves, having three nerves, the scales of the empalement being erect, and as long as the disk of the flower. Corona solis Caroliniana, parvis floribus, folio trinervi amplo aspero, pediculo alato. Martyn. Cent. 1. 20. Carolina Sun-flower with small flowers, large rough leaves having three veins, and a winged foot-stalk.
10. **HELIANTHUS** (*Decapetalus*) caule infernè lævi, foliis lanceolato-cordatis, radiis decapetalis. Lin. Sp. Plant. 905. Sun-flower with a smooth stalk, heart spear-shaped leaves, smooth on their upper side, and ten petals in the rays.

All these species of Sun-flowers are natives of America, from whence we are often supplied with new kinds; and it is very remarkable, that there is not a single species of this genus that is European; so that before America was discovered, we were wholly unacquainted with these plants. But although they are not originally of our own growth, yet they are become so familiar to our climate, as to thrive and increase full as well as if they were in their native country, (some of the very late flowering kinds excepted, which require a longer summer than we generally enjoy, to bring them to perfection;) and many of them are now so plentiful in England, that persons unacquainted with the history of these plants, would imagine them at least to have been inhabitants of this island many hundred years; particularly the *Jerusalem Artichoke*, which, though it doth not produce seeds in our climate, yet doth so multiply by its knobbed roots, that, when once well fixed in a garden, it is not easily to be rooted out.

The first sort is annual, and so well known as to require no description. There are single and double flowers of two different colours, one of a deep yellow, and the other of a sulphur colour; but these vary, so are not worthy to be mentioned as different. They are easily propagated by seeds, which should be sown in March, upon a bed of common earth; and when the plants come up, they must be thinned where they are too close, and kept clean from weeds; when

the plants are grown six inches high, they may be taken up with balls of earth to their roots, and planted into the large borders of the pleasure-garden, observing to water them till they have taken new root; after which they will require no other care, but to keep them clear from weeds.

In July the great flowers upon the tops of the stems will appear, amongst which, the best and most double flowers of each kind should be preserved for seeds; for those which flower later upon the side branches are neither so fair, nor do they perfect their seeds so well, as those which are first in flower: when the flowers are quite faded and the seeds are formed, you should carefully guard the heads from the sparrows, which will otherwise devour most of the good seeds; and about the beginning of October, when the seeds are ripe, you should cut off the heads with a small part of the stem, and hang them up in a dry airy place for about a month, by which time the seeds will be perfectly dry and hard; when you may easily rub them out, and put them into bags or papers, preserving them from vermin until the season for sowing them.

The seeds of this sort of Sun-flower are excellent food for domestic poultry; therefore where a quantity of it can be saved, it will be of great use, where there are quantities of these fowls.

The other perennial sorts rarely produce seeds in England, but most of them increase very fast at their roots, especially the creeping rooted kinds, which spread too far for small gardens. The second sort, which is the most common in the English gardens, is the largest and most valuable flower, and is a very proper furniture for large borders in great gardens, as also for bosquets of large growing plants, or to intermix in small quarters with shrubs, or in walks under trees, where few other plants will thrive; it is also a great ornament to gardens within the city, where it grows in defiance of the smoke, better than most other plants; and for its long continuance in flower, deserves a place in most gardens, for the sake of its flowers for basons, &c. to adorn halls and chimneys, in a season when we are at a loss for other flowers. It begins flowering in July, and continues until October; there is a variety of this with very double flowers, which is now become so common in the English gardens, as to have almost banished the single sort from hence.

The third, fourth, fifth, sixth, and seventh sorts may also have a place in some large borders of the garden, for the variety of their flowers; which, though not so fair as those of the common sort, yet will add to the diversity; and as many of them are late flowerers, so we may continue the succession of flowers longer in the season.

These sorts are all of them very hardy, and will grow in almost any soil or situation; they are propagated by parting their roots into small heads, which in one year's time will spread and increase greatly. The best season for this work is in the middle of October, soon after the flowers are past, or very early in the spring, that they may be well rooted before the droughts come on; otherwise their flowers will be few in number, and not near so fair, and by this means their roots will be weak; but if they are planted in October, you will save the trouble of watering them; their roots being surely fixed before the dry weather, they will need no other trouble than to clear them from weeds.

The Jerusalem Artichoke is propagated in many gardens for the roots, which are by some people as much esteemed as Potatoes; but they are more watery and flashy, and are very subject to trouble the belly by their windy quality, which hath brought them almost into disuse.

These are propagated by planting the smaller roots, or the larger ones cut in pieces, observing to preserve a bud to each separate piece, either in the spring or autumn, allowing them a good distance, for their roots will greatly multiply; the autumn following,

when their stems decay, the roots may be taken up for use. These should be planted in some remote corner of the garden, for they are very unlighty while growing, and their roots are apt to over-run whatever grows near them, nor can they be easily destroyed when they are once well fixed in a garden.

The other species which have been ranged under this genus by Tournefort and others, are now removed to the following genera, under which titles they may be found.

Corona Solis. See { COREOPSIS.
HELENUM.
RUDBECKIA.
SILPHIUM.

HELICTERES. Lin. Gen. Plant. 913. Ifora. Plum. Nov. Gen. 34. tab. 37. Screw-tree.

The CHARACTERS are,

The flower has a coriaceous empalement of one leaf, which is narrow at bottom, but spreads open at the top, where it is indented in five parts. The flower hath five oblong equal petals, which are longer than the empalement to which they are fixed. It hath ten short stamina at the base of the germen, terminated by oblong summits, and five nectariums surrounding the germen, which have the appearance of petals. The style is very long, slender, and supports the germen at the top, which is roundish, and crowned by an acute stigma. The germen afterward turns to a twisted spiral fruit with one cell, inclosing many kidney-shaped seeds.

This genus of plants is ranged in the sixth section of Linnæus's twentieth class, which includes those plants whose flowers have ten stamina which are connected to the style.

The SPECIES are,

1. HELICTERES (*Ifora*) foliis cordato-ovatis ferratis, subtus tomentosis, fructu tereti contorto. *Helicteres with oval heart-shaped leaves which are sawed, and woolly on their under side, and a taper twisted fruit. Ifora althææ foliis, fructu longiore & angustiore. Plum. Nov. Gen. 24. Screw-tree with Marshmallow leaves, and a longer narrower fruit.*
2. HELICTERES (*Breviore*) foliis cordatis acuminatis serratis, subtus tomentosis, fructu brevi contorto. *Helicteres with heart-shaped, pointed, sawed leaves, woolly on their under side, and a short twisted fruit. Ifora althææ foliis, fructu brevior & crassior. Plum. Nov. 34. Screw-tree with a Marshmallow leaf, and a shorter thicker fruit.*
3. HELICTERES (*Arborescens*) caule arboreo villoso, foliis cordatis crenatis nervosis subtus tomentosis fructu ovato contorto villosissimo. *Helicteres with a tree-like hairy stalk, heart-shaped, nervous, crenated leaves, woolly on their under side, and an oval, twisted, very hairy fruit. Ifora althææ folio amplissimo, fructu crassissimo & villoso. Edit. prior. Screw-tree with a very large Marshmallow leaf, and a very thick hairy fruit.*

The first sort grows naturally in the Bahama Islands, from whence I received the seeds. This rises with a shrubby stalk five or six feet high, sending out several lateral branches, which are covered with a soft yellowish down, garnished with heart-shaped leaves four inches long, and two and a half broad, sawed on their edges, woolly on their under side, standing on long foot-stalks; at the upper part of the branches the flowers come out opposite to the leaves, upon slender foot-stalks which are jointed; these are composed of five oblong white petals, and in the center arises the style, which is curved, three inches long, upon the top of which is situated the germen, crowned by an acute stigma. The germen afterward turns to a taper fruit two inches and a half long, composed of five capsules, which are closely twisted over each other like a screw; these are hairy, and have each one cell, containing several kidney-shaped seeds.

The second sort grows naturally in Jamaica, from whence the late Dr. Houstoun sent me the seeds. This rises with a shrubby stalk nine or ten feet high, sending out many lateral branches, covered with a smooth brown bark, garnished with heart-shaped leaves,

HEL

leaves, which end in acute points, sawed on their edges, a little woolly on their under side; the flowers are produced on the side of the branches, on shorter foot-stalks than the former; they are composed of five petals, and the style in the center, which is strait, upright, and not half so long as the other; the fruit is thicker, not an inch long, but twisted in the same manner,

The third sort rises with a strong woody stalk twelve or fourteen feet high, sending out many ligneous branches, which are closely covered with hairy down, garnished with large heart-shaped leaves, which are crenated on their edges, having large veins running from the midrib to the sides; they are of a light yellowish green, and woolly on their under side: the flowers are produced from the side of the branches, they are of a yellowish white colour, and larger than those of the other sorts. The style is near four inches long, curved like that of the first sort; the fruit is oval, about one inch long, very thick at the bottom, and closely covered with hairy down. This sort was sent me by Mr. Robert Millar, from Carthage.

These plants are propagated by seeds, which must be sown upon a hot-bed in the spring, and when the plants are come up strong enough to remove, they should be each planted in a separate small pot, filled with light earth, and plunged into a moderate hot-bed of tan, observing to shade them from the sun till they have taken new root; then they should be treated in the same way as other tender plants from hot countries, raising the glasses every day in proportion to the weather, that the plants may enjoy fresh air, which will strengthen them, and prevent their drawing up weak. In the summer the plants may remain under the frames, if there is sufficient height for them to grow; but in autumn they must be plunged into the tan-bed in the stove, where they should always remain, being careful to shift them into larger pots when they require it, and not give them too much wet in the winter; but in summer they should have a large share of air in warm weather, and require to be often refreshed with water: the second year from the seeds these plants have often flowered in the Chelsea garden, and the seeds have some years ripened there, but the plants will live several years with proper management.

HELIOCARPOS. Lin. Gen. Plant. 533. Montia. Houst. Gen. We have no title in English for this plant.

The CHARACTERS are,

The flower hath one petal which is tubulous at the bottom, and cut into five segments which expand. It hath an empalement of one leaf, which is cut into five parts spreading open. In the center is situated a roundish germen, supporting two erect styles, crowned by acute stigmas which stand apart; these are attended by twelve stamina, which are of the same length with the styles, terminated by narrow twin summits which are prostrate. The germen afterward becomes an oval compressed capsule, about three lines long and two broad, with a transverse partition dividing it in two cells, each containing a single roundish seed ending in a point; the borders of the capsule are set with hairs, resembling rays.

This genus of plants is ranged in the second section of Linnaeus's eleventh class, intitled Dodecandria Digynia, which includes the plants whose flowers have twelve stamina and two styles.

We have but one SPECIES of this plant, viz.

HELIOCARPOS (*Americana.*) Hort. Cliff. 211. tab. 16. *Montia arborefcens mori folio fructu racemoso.* Houst. MSS. *Tree Montia with a Mulberry leaf and branching fruit.*

This plant was discovered by the late Dr. Houstoun, growing naturally about Old La Vera Cruz in New Spain, from whence he sent the seeds to England, which succeeded in the Chelsea garden, where the plants have produced flowers, and ripened seeds several years. It rises with a thick, soft, woody stalk, from fifteen to eighteen feet high, sending out seve-

HEL

ral lateral branches toward the top, garnished with heart-shaped leaves full of veins, sawed on their edges, and ending in acute points; they have foot-stalks three inches long, which stand oblique to the leaves, and are placed alternate; the flowers are produced at the end of the shoots, in branching clusters; they are of a yellowish green, and are succeeded by flat compressed seed-vessels of an oval shape, whose borders are closely set with threads representing rays, of a brownish colour when ripe; these capsules are divided into two cells by an intermediate partition, in each of these is lodged a single roundish seed ending in a point.

This plant is propagated by seeds, which must be sown upon a hot-bed in the spring; and when the plants are fit to remove, they should be each planted in a separate small pot filled with light kitchen-garden earth, and plunged into a hot-bed, treating them in the same way as other tender plants, which will not bear the open air in this country at any season of the year; and while the plants are young, they require to be plunged in the tan-bed, but after they have acquired strength, they will thrive in the dry stove. In winter they should have but little water, and must be kept warm; but in summer they should have plenty of fresh air in mild weather, and must be frequently refreshed with water. With this management the plants will flower the third year, and produce good seeds, but may be preserved several years with proper care.

I have sowed the seeds of this plant which had been kept ten years, and came up as well as if it had been saved the former year; though from the appearance of the seeds, it seems as unlike to grow after the first year as any which I know.

HELIOPHILA. Lin. Gen. 816.

The CHARACTERS are,

It hath a four-leaved empalement, whose borers have membranes; the two outer have small bladders at their base. The flower has four roundish plain petals, placed in form of a cross, and two nectariums, which are recurved toward the bladders of the empalement. It hath six stamina, four of which are longer than the other, terminated by oblong erect summits; and a cylindrical germen supporting a short style, crowned by an obtuse stigma; the germen afterward becomes a taper pod, with two cells filled with seeds.

This genus of plants is ranged in the second section of Linnaeus's fifteenth class, intitled Tetradynamia Siliquosa, the flower having four long and two short stamina, and the seeds being included in long pods.

The SPECIES are,

1. **HELIOPHILA** (*Integrifolia*) foliis lanceolatis indivisis. N. Burman. *Heliophila with spear-shaped undivided leaves.* Leucoium Africanum, coeruleo flore, latifolium. H. L. 364. *African Gilliflower with a broad leaf and a blue flower.*
2. **HELIOPHILA** (*Coronopifolia*) foliis linearibus pinnatifidis. Lin. Sp. Plant. 927. *Heliophila with linear wing-pointed leaves.* Leucoium Africanum, coeruleo flore, angusto coronopi folio majus. H. L. 364. *African Gilliflower, with narrow Hartshorn leaves and blue flowers.*

These are both annual plants, which grow naturally at the Cape of Good Hope; the first rises with an erect stalk about four or five inches high, sending out two or three side branches, garnished with long, narrow, entire green leaves, and terminated by a loose bunch of blue flowers without scent, which are succeeded by taper pods near three inches long, having a double row of flat seeds.

The second sort grows about the same height, but branches more; the leaves are cut into many wing-pointed divisions, and the flowers are like those of the other sort.

The seeds of both sorts may be sown in the spring on a south border, and when the plants come up, if they are thinned and kept clean from weeds, it is all the culture they require.

HELIO-

HELIOTROPIUM. Lin. Gen. Plant. 164. Tourn. Inst. R. H. 138. tab. 57. [*ἡλιοτρόπιον*, of *ἥλιος*, the sun, and *τρέπω*, to turn.] Turnsole.

The CHARACTERS are,

The empalement of the flower is of one leaf, tubulous at bottom, but cut into five segments at the brim. The flower hath one petal, with a tube the length of the empalement, spreading flat above, where it is cut into five segments, which are alternately larger than the other; the chaps of the tube is closed, and hath five prominent scales, joined in form of a star. It hath five short stamina within the tube, terminated by small summits, and four germen at the bottom of the tube, with one slender style the length of the stamina, crowned by an indented stigma. The germen afterward becomes so many seeds, sitting in the empalement. This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which includes those plants whose flowers have five stamina and one style.

The SPECIES are,

1. **HELIOTROPIUM** (*Europæum*) foliis ovatis integerrimis tomentosis rugosis spicis conjugatis. Hort. Upsal. 33. *Heliotrope with oval, entire, woolly, rough leaves, and conjugated spikes. Heliotropium majus Dioscoridis. C. B. P. 253. The greater Turnsole of Dioscorides.*
2. **HELIOTROPIUM** (*Indicum*) foliis cordato-ovatis acutis scabriusculis, spicis solitariis, fructibus bifidis. Flor. Zeyl. 70. *Heliotrope with heart-shaped oval leaves, which are pointed and rough, single spikes of flowers and bifid seeds. Heliotropium Americanum cœruleum, foliis hormini. Acad. Reg. Sc. Blue American Turnsole with Clary leaves.*
3. **HELIOTROPIUM** (*Horminifolium*) foliis lanceolato-ovatis acuminatis rugosis, spicis solitariis gracilioribus alaribus & terminalibus. *Heliotrope with spear-shaped oval leaves, which are rough, and end in acute points, having slender single spikes of flowers proceeding from the sides and tops of the stalks. Heliotropium Americanum cœruleum, foliis hormini angustioribus. H. L. Blue American Turnsole with narrower Clary leaves.*
4. **HELIOTROPIUM** (*Capitatum*) foliis oblongo-ovatis integerrimis glabris subtus incanis, floribus capitatis alaribus, caule arborescente. *Heliotrope with oblong, oval, entire, smooth leaves, which are hoary on their under side, flowers growing in beads from the wings of the stalks, and a tree-like stalk. Heliotropium arborescens, folio teucii, flore albo in capitula densa congesto. Boerh. Ind. Tree-like Turnsole, with a Germander leaf, and white flowers growing in thick short beads.*
5. **HELIOTROPIUM** (*Canariense*) foliis ovatis crenatis oppositis, floribus capitatis alaribus dichotomis, caule arborescente. *Heliotrope with oval crenated leaves placed opposite, flowers growing in beads from the wings of the stalks, which diverge, and a tree-like stalk. Heliotropium Canariense arborescens, folio scorodonzæ. Hort. Amst. Canary tree-like Turnsole, with a Wood Sage leaf.*
6. **HELIOTROPIUM** (*Peruvianum*) foliis lanceolato-ovatis, caule fruticoso, spicis numerosis aggregato-corymbosis. Lin. Sp. 187. *Peruvian Heliotrope with oval spear-shaped leaves, a shrubby stalk, and many spikes of flowers joined in a corymbus.*
7. **HELIOTROPIUM** (*Curassavicum*) foliis lanceolato-linearibus glabris aveniis, spicis conjugatis. Hort. Cliff. 45. *Heliotrope with narrow, spear-shaped, smooth leaves without veins, and conjugated spikes of flowers. Heliotropium Curassavicum, foliis lini umbilicati. Par. Bat. Prod. Heliotrope of Curassao, with a Venus Navelwort leaf.*
8. **HELIOTROPIUM** (*Gnaphalodes*) foliis linearibus obtusis tomentosis, pedunculis dichotomis, spicarum floribus quaternis, caule frutescente. Lin. Sp. 188. *Heliotrope with linear, obtuse, woolly leaves, forked foot-stalks, with four spikes of flowers and a shrubby stalk. Heliotropium arboreum maritimum, tomentosum, gnaphalii Americani foliis. Sloan. Cat. 93. Tree maritime woolly Heliotrope, with a Sea Cudweed leaf.*
9. **HELIOTROPIUM** (*Fruticosum*) foliis linearilanceolatis pilosis, spicis solitariis sessilibus. Lin. Sp. 187. *Heliotrope with linear, spear-shaped, hairy leaves, and single spikes of flowers sitting close to the stalk. Heliotropium*

minus lithospermi foliis. Smaller Heliotrope with leaves like Gromwell.

10. **HELIOTROPIUM** (*Procumbens*) caule procumbente, foliis ovatis tomentosis integerrimis, spicis solitariis terminalibus. *Heliotrope with a trailing stalk, oval, woolly, entire leaves, and single spikes of flowers terminating the branches. Heliotropium Americanum supinum & tomentosum, foliis subrotundis. Houst. MSS. Low American woolly Heliotrope with roundish leaves.*

11. **HELIOTROPIUM** (*Americanum*) foliis oblongo-ovatis tomentosis, spicis conjugatis terminalibus, caule fruticoso. *Heliotrope with oblong, oval, woolly leaves, and double spikes of flowers terminating the stalk, which is shrubby. Heliotropium Americanum frutescens & tomentosum, foliis oblongis, floribus albis. Houst. MSS. Shrubby and woolly American Heliotrope, with oblong leaves and white flowers.*

The first sort grows naturally in the south of France, in Spain, Italy, and most of the warmer countries in Europe. It is an annual plant, which succeeds better from seeds which scatter in the autumn, or sown at that season, than in the spring; for when they are sown in the spring, they seldom come up the same year; but if the plant is once obtained, and the seeds suffered to shed, it will maintain itself without any trouble, requiring no other culture but to keep it clean from weeds, and thin the plants where they are too close.

This rises about seven or eight inches high, dividing into two or three branches, garnished with oval rough leaves, two inches long and one broad in the middle, of a light green, standing upon pretty long foot-stalks alternately; the flowers are produced at the end of the branches in double spikes, joined at the bottom, which are about an inch and a half long, turning backward like a scorpion's tail. The flowers are white, and appear in June and July; the seeds ripen in autumn, soon after which the plant decays.

The second sort grows naturally in the West-Indies. This is annual; the stalk rises a foot and a half, or two feet high, branching out toward the top: the leaves are rough and hairy, standing upon pretty long foot-stalks; they are two inches and a half long, and one and a half broad in the middle, ending in acute points; the flowers are produced toward the end of the branches in single spikes, which are six inches long, turning backward at the top like the other species. The flowers are blue, and appear in July and August, the seeds ripen in September and October.

The third sort grows naturally in the West-Indies. This is a smaller plant than the former, seldom growing above two feet high; the leaves are one inch and a half long, and about half an inch broad; the spikes of flowers are very slender, and not more than two inches long; the flowers are small, and of a light blue colour. They appear at the same time with the former, and the seeds ripen in autumn.

The seeds of these two sorts must be sown on a hot-bed in the spring, and when the plants are fit to remove, they must be transplanted on another hot-bed to bring them forward, treating them in the same way as the Balsamine, and other tender annual plants; and in June they may be taken up with balls of earth, and planted in the borders of the flower-garden, where they will flower, and in warm seasons produce ripe seeds.

The fourth sort rises with a shrubby stalk six or seven feet high; the young branches are closely covered with a white down, and the leaves on those are very hoary and entire, but those on the older branches are greener, and some of them are notched on their edges; at each joint of the stalks come out two short branches opposite, which are garnished with small hoary leaves placed opposite: these, when bruised, emit a strong odour, which to some persons is very disagreeable, but others are pleased with it. The plants rarely flower in England, for in near forty years which I have cultivated them, I have but once seen them in flower. The flowers are white, collected in roundish heads, which turn backward, and sit close to the branches;

the leaves continue all the year, for which the plants are preserved in green-houses, to add to the variety in winter.

The fifth sort grows naturally in the Canary Islands. This rises with a woody stalk three or four feet high, dividing into many branches, which are garnished with oval leaves notched on their edges, growing opposite upon long foot-stalks; they are hairy, and of an Ash colour on their under side; the flowers are produced from the side of the branches on pretty long foot-stalks, each sustaining four short roundish spikes or heads, which divide by pairs, and spread from each other. The flowers are white, and appear in June and July, but are not succeeded by seeds in England. The leaves of this plant, when bruised, emit an agreeable odour, for which it is by some persons much esteemed; the gardeners have given it the title of *Madam Maintenon*, but for what reason I know not.

The two last sorts are too tender to live through the winter in the open air in this country, so must be kept in a green-house during that season; but they only require to be screened from frost, so may be placed with Myrtles and the other hardy green-house plants, where they may have a large share of air in mild weather, and be treated in the same way; they are easily propagated by cuttings during any of the summer months, which, if planted in a shady border and duly supplied with water, will take root in five or six weeks; then they may be potted, and placed in a shady situation till they have taken new root, after which they may be treated as the old plants.

The sixth sort grows naturally in Peru, from whence the seeds were sent by the younger Jussieu to the Royal Garden at Paris, where the plants produced flowers and seeds; and from the curious garden of the Duke D'Ayen, at St. Germain, I was supplied with some of the seeds, which have succeeded in the Chelsea garden, where the plants have flowered and perfected their seeds for some years.

This rises with a shrubby stalk two or three feet high, dividing into many small branches, garnished with oval, spear-shaped, rough leaves, set on without order; they are three inches long, and one inch and a half broad in the middle, standing on short foot-stalks; they are hairy, and greatly veined on their under side, which is of an Ash colour. The flowers are produced at the end of the branches in short reflexed spikes, growing in clusters. The foot-stalks divide into two or three, and these divide again into less, each sustaining a spike of pale blue flowers, which have a strong sweet odour. The plants continue in flower great part of the year, and those flowers which come out in summer, are succeeded by ripe seeds in autumn.

It may be propagated either by seeds or cuttings. The seeds should be sown upon a moderate hot-bed in the spring, and when the plants are fit to remove, they should be transplanted into small pots filled with light earth, and plunged into a hot-bed, where they should be shaded till they have taken new root; then they should be inured to the open air by degrees, into which they should be removed in summer, placing them in a sheltered situation; and in autumn they must be housed with other exotic plants in a good green-house, where they will flower great part of winter, so will make a good appearance among the Orange-trees, and other green-house plants, with whose culture this plant will thrive. If the cuttings of this plant are put into pots filled with light earth, during any of the summer months, and plunged into a moderate hot-bed, they will take root very freely, but these do not make so good plants as those raised from seeds.

The seventh sort grows naturally on the sea-shore in the West-Indies; this is an annual plant, whose branches trail upon the ground, and grow a foot long; they are garnished with narrow grayish leaves, which are smooth. The flowers are produced in double spikes

from the side of their branches; they are white and small, so make no great appearance. It is propagated by seeds, and requires the same treatment as the second and third sorts.

The eighth sort rises with an upright woody stalk six or seven feet high, with a hoary bark, full of marks where the leaves have grown; the upper part of the stalk divides into two or three strong woody branches, which grow erect, and are very closely garnished with long, narrow, woolly leaves, which stand on every side the branches without order. The flowers come out from the side of the stalks, to which they sit close; they are short and reflexed, like those of the other species. The flowers are purple, sitting in very woolly empalements, which are divided into five segments, which spread open; the whole plant is very white and woolly, like the Sea Cudweed, so makes an odd appearance when intermixed with other exotic plants: this is propagated by seeds, which must be procured from the places where it naturally grows, for it never produces any in Europe; these seeds should be sown in a tub of earth in the country, for when the dried seeds come over they seldom grow; and if they do, it is not before the second year: and from several parcels of the seeds which I have received from the West-Indies, I have not raised more than two plants, and these came up from the seeds which had been sown more than a year; so that if the seeds are sown as soon as they are ripe in a tub of earth, when they arrive in England, the tub should be plunged into a hot-bed of tanners bark, which will bring up the plants; and when these are fit to remove, they should be each planted in a separate small pot filled with earth, composed of sand and light undunged earth, with a little lime rubbish well mixed together, then plunged into a hot-bed of tanners bark, and shaded until they have taken new root; after which, they must be treated as other tender exotic plants, always keeping them in the tan-bed in the stove, giving them but little water, especially during the winter season.

The ninth sort is a native of the West-Indies, where it grows plentifully on the sea-shore; it rises with an upright shrubby stalk a foot and a half high, garnished with small spear-shaped leaves, scarce one inch long, and one-third of an inch broad in the middle, ending in acute points, sitting close to the stalk; they are hoary on their under side, but smooth above. The flowers are produced in single slender spikes, which come out from the side, and at the top of the stalks; they are but little recurved, especially those on the side, but those at the top are more bent; they are white, so make but little appearance.

The tenth sort was sent me from Carthagena in New Spain, where it grows naturally on the sandy shores. This is an annual plant, with trailing stalks which grow six or seven inches long, garnished with small oval leaves, which are woolly and entire. The flowers are produced at the end of the branches, in single short spikes, which are reflexed; they are small and white, so make little appearance.

The eleventh sort was sent me by the late Dr. Houstoun from La Vera Cruz, where he found it growing in plenty; this rises with a shrubby stalk three feet high, dividing into slender branches, which are closely garnished with oblong, oval, woolly leaves, placed without order. The flowers are produced at the end of the branches in double spikes, which are slender, short, and strait, not recurved as the other species. The flowers are small and white, and the plant is perennial.

These three last mentioned are propagated by seeds, but the difficulty of getting them fresh from America, and the uncertainty of their growing, unless they are sown abroad, and brought over in earth, has rendered them rare in Europe; and as they are plants of little beauty, so few persons have taken the trouble to procure them: besides, as they require a stove to preserve them in this country, and must have a peculiar soil

HEL

and management like the eighth sort, so, unless for the sake of variety in botanic gardens, they are not worth cultivating here.

HELLEBORE. See HELLEBORUS.

HELLEBORINE. See SERAPIAS and LIMADORUM.

HELLEBOROIDES HYEMALIS. See HELLEBORUS.

HELLEBORO RANUNCULUS. See TROLLIUS.

HELLEBORUS. Lin. Gen. Plant. 622. Tourn. Inst. R. H. 271. tab. 144. [*Ελληβορος*.] Black Hellebore, or Christmas flower; in French, *Ellebore-Noire*.

The CHARACTERS are,

The flowers hath no empalement; it hath five large roundish petals, which are permanent, and many small nectarii placed circularly, each being of one piece, with a narrow tube at the bottom, divided at the brim into two lips, the under being short and indented; it hath a great number of stamina, terminated by compressed erect summits, and several germen, which are compressed, supporting awl-shaped styles, crowned by thick stigmas. The germen afterward turn to compressed capsules with two keels, the lower being short, and the upper convex, which are filled with round seeds adhering to the seam.

This genus of plants is ranged in the seventh section of Linnæus's thirteenth class, intitled Polyandria Polygynia, which includes those plants whose flowers have many stamina and styles.

The SPECIES are,

1. HELLEBORUS (*Fœtidus*) caule multifloro folioso, foliis pedatis. Lin. Sp. Plant. 784. *Hellebore with many flowers on a stalk, which are intermixed with leaves, and ramose leaves sitting on the foot-stalk. Helleborus niger fœtidus. C. B. P. Stinking Black Hellebore, Bears-foot, or Setterwort.*
2. HELLEBORUS (*Viridis*) caule multifloro folioso, foliis digitatis. Lin. Sp. Plant. 558. *Hellebore with many flowers on a stalk, which are intermixed with leaves, and hand-shaped leaves. Helleborus niger hortensis, flore viridi. C. B. P. Green flowered Black Hellebore, or Bears-foot.*
3. HELLEBORUS (*Niger*) scapo sub-unifloro sub-nudo, foliis pedatis. Hort. Upsal. 157. *Hellebore with one flower on a stalk, which is naked, and hand-shaped leaves sitting on the foot-stalk. Helleborus niger, flore albo, etiam interdum valde rubente. J. B. True Black Hellebore, or Christmas Rose.*
4. HELLEBORUS (*Trifolius*) caule multifloro, foliis ternatis integerrimis. *Hellebore with many flowers on a stalk, and leaves composed of three entire lobes. Helleborus niger trifolius. Hort. Farn. Trifoliate Black Hellebore.*
5. HELLEBORUS (*Hyemalis*) flore folio insidente. Hort. Cliff. 227. *Hellebore with the flower sitting on the leaf. Aconitum Hyemale, or Winter Aconite.*
6. HELLEBORUS (*Latifolius*) caule multifloro folioso, foliis digitatis serratis amplioribus. *Hellebore with many flowers upon a stalk, intermixed with leaves, and large fingered leaves which are sawed. Helleborus niger amplioribus foliis. Tourn. Inst. R. H. 272. Black Hellebore with larger leaves.*

The first sort grows naturally in woods in several parts of England, but particularly in Suffex, where I have seen it in great plenty; this hath a jointed herbaceous stalk, which rises two feet high, dividing into two or three heads, garnished with leaves composed of eight or nine long narrow lobes, which join at their base; four of these on each side are joined together at their tails, and the middle one stands on the center of the foot-stalk; these are sawed on their edges, and end in acute points; those on the lower part of the stalk are much larger than the upper, which are small and narrow. The flower-stalk arises from the center of the plant, dividing into many branches, each sustaining several smaller foot-stalks, with one entire spear-shaped leaf upon each, and one large greenish flower at the top with purplish rims;

HEL

these appear in winter, and the seeds ripen in the spring; which, if permitted to scatter, the plants will rise without care, and may be transplanted into woods, or in wilderness quarters, where they will grow in great shade, and make a good appearance at a season when there are but few plants in beauty.

The second sort grows naturally at Ditton, near Cambridge, and in the woods near Stoken Church, in Oxfordshire. The stalks of this sort grow more upright than those of the first, and do not branch so much. The leaves are composed of nine long lobes, which unite to the foot-stalk at their base, and are sharply sawed on their edges; they are of a lighter green than those of the first sort. The flowers are produced at the top of the stalk, having one or two leaves set on the foot-stalk; they are composed of five oval green petals, with a great number of stamina surrounding the germen in the middle; these appear the beginning of February, and the seeds ripen the end of May, which if sown soon after they are ripe, the plants will come up early the following spring; and, when they have obtained strength, may be planted in shady places under trees, where they will thrive and flower very well. The leaves of this sort decay in autumn, and new ones arise from the roots in the spring, but the first sort is always green.

The third sort is supposed to be the Hellebore of the ancients; this grows naturally on the Alps and Apennine mountains. The root of this sort is composed of many thick fleshy fibres, which spread far into the ground, from which arise the flowers upon naked foot-stalks, immediately from the root, each supporting one large white flower, composed of five roundish petals, with a great number of stamina in the middle. The leaves of this are composed of seven or eight thick, fleshy, obtuse lobes, which are slightly sawed on their edges, and unite with the foot-stalk at their base; this plant flowers in winter, from whence the title of Christmas Rose was applied to it: it is propagated by parting of the roots in autumn, for the seeds seldom ripen well in England; it should have a more sheltered situation than either of the former, otherwise it will not flower well.

The fourth sort is like the second, but differs from it in having trifoliate leaves, which are broader and entire, their surface is smoother; this flowers early in winter, and the stalks rise higher than either of the former sorts, but is at present rare in England.

The fifth sort is the common Winter Aconite, which is so well known as to need no description. It flowers very early in the spring, which renders it worthy of a place in all curious gardens, especially as it requires but little room; this is propagated by offsets, which the roots send out in plenty; these roots may be taken up and transplanted, any time after their leaves decay, which is generally by the beginning of June till October, when they will begin to put out new fibres; but as the roots are small, and nearly of the colour of the ground, so, if care is not taken to search them, many of the roots will be left in the ground; these roots should be planted in small clusters, otherwise they will not make a good appearance; for single flowers scattered about the borders of these small kinds, are scarce seen at a distance; but when these and the Snowdrops are alternately planted in bunches, they will have a good effect, as they flower at the same time, and are much of a size.

The sixth sort is like the first, but the lobes of the leaves are broader, and the stalks grow taller; this grows naturally in Istria and Dalmatia, from whence I received some of the seeds; it has been supposed to be only a seminal variety of the first, and as such I sowed the seeds; but the plants had a very great difference, and the first winter proving severe, they were all destroyed; so that it is not so hardy as our common sort, and depending on their being so, occasioned the loss of the plants.

HEMEROCALLIS. Lin. Gen. Plant. 391. Lilio-Asphodelus. Tourn. Inst. R. H. 344. tab. 179. Liliastrum. Tourn. Inst. R. H. 369. tab. 194. *Lily Asphodel, or Day Lily*; in French, *Lis de Saint Bruno*.

The CHARACTERS are,

The flower has no empalement; in some species the flower is of one petal, cut into six parts; in others it hath six petals, with a short tube, spreading open at the top, which is reflexed. There are six awl-shaped declining stamina surrounding the style, terminated by oblong prostrate summits. The roundish furrowed germen is situated in the middle, supporting a slender style, crowned by an obtuse three-cornered stigma. The germen afterward becomes an oval three-cornered capsule with three lobes, opening with two valves, filled with roundish seeds.

This genus of plants is ranged in the first section of Linnæus's sixth class, which includes the plants whose flowers have six stamina and one style. Tournefort places the first in the first section of his ninth class, which includes the plants with a Lily-flower of one leaf, cut into six parts, whose pointal becomes the fruit; the second he places in his fourth section of the same class, with the flowers of the same form which have six petals.

The SPECIES are,

1. HEMEROCALLIS (*Flava*) corollis flavis. Lin. Sp. 462. Hort. Upsal. 88. *Day Lily with a yellow flower*. Lilio-Asphodelus luteus. Park. Par. 148. *Yellow Asphodel Lily*.
2. HEMEROCALLIS (*Minor*) scapo compresso corollis monopetalis campanulatis. *Day Lily with a compressed stalk, and a bell-shaped flower of one petal*. Lilio-Asphodelus luteus, minor. Tourn. Inst. R. H. 344. *Smaller yellow Asphodel Lily*.
3. HEMEROCALLIS (*Fulva*) corollis fulvis. *Day Lily with a copper-coloured flower*. Lilio-Asphodelus phoenicius. Park. Par. 148: *Asphodel Lily with a reddish flower*.
4. HEMEROCALLIS. (*Liliastrum*) scapo simplici, corollis hexapetalis campanulatis. Hort. Cliff. 128. *Day Lily with an unbranched single stalk, and bell-shaped flowers with six petals*. Liliastrum Alpinum majus. Tourn. Inst. R. H. 369. *Greater Alpine Bastard Lily, called Savoy Spiderwort*; and in French, *Lis de Saint Bruno, i. e. St. Bruno's Lily*.

The first sort grows naturally in Hungary, Dalmatia, and Istria, but has long been an inhabitant in the English gardens; this hath strong fibrous roots, to which hang knobs, or tubers, like those of the Asphodel, from which come out keel-shaped leaves, which are two feet long, with a rigid midrib, the two sides drawing inward, so as to form a sort of gutter on the upper side. The flower-stalks rise two feet and a half high, having two or three longitudinal furrows; these are naked, and at the top divide into three or four short foot-stalks, each sustaining one pretty large yellow flower shaped like a Lily, having but one petal, with a short tube, spreading open at the brim, where it is divided into six parts; these have an agreeable scent, from which some have given it the title of yellow Tuberosè. It flowers in June, and the seeds ripen in August; this plant is easily propagated by offsets, which the roots send out in plenty; these may be taken off in autumn, that being the best season for transplanting the roots, and planted in any situation, for they are extremely hardy, and will require no other culture but to keep them clean from weeds, and to allow them room that their roots may spread; they may also be propagated by seeds, which, if sown in autumn, the plants will come up the following spring; and these will flower in two years; but if the seeds are not sown till spring, the plants will not come up till the year after.

The second sort grows naturally in Siberia; this hath roots like those of the former sort, but are smaller. The leaves are not near so long, nor more than half the breadth of the former, and of a dark green co-

H E M

lour. The flower-stalk rises a foot and a half high, is naked and compressed, but has no furrows; at the top is produced two or three yellow flowers, which are nearer the bell-shape than those of the other species, and stand on shorter foot-stalks; these flower the beginning of June, and the seeds ripen early in August. It is propagated by offsets from the root, or by seeds, in the same manner as the former, but the roots do not increase so fast; it should have a moist soil and a shady situation, where it will thrive much better than in dry ground.

The third sort is a much larger plant than either of the former, and the roots spread and increase much more, therefore is not proper furniture for small gardens; the roots of this hath very strong fleshy fibres, to which hang large oblong tubers. The leaves are near three feet long, hollowed like those of the former, turning back toward the top. The flower-stalks are as thick a man's finger, and rise near four feet high; they are naked, without joints, and branching at the top, where are several large copper-coloured flowers, shaped like those of the Red Lily, and as large. The stamina of this sort are longer than those of the other, and their summits are charged with a copper-coloured farina, which sheds on being touched; or if a person smells to the flowers, it will fly off and spread over the face, dyeing it all over of a copper colour, which is a trick often played by some unlucky people to the ignorant: these flowers never continue longer than one day, but there is a succession of flowers on the same plants for a fortnight or three weeks; this sort flowers about the same time as the former, and the roots propagate too fast for those gardens where there is but little room. It will grow on any soil or in any situation; the best time to transplant the roots is in autumn.

The Savoy Spiderwort, or, as the French call it, St. Bruno's Lily, is a plant of humbler growth than either of the former: there are two varieties of this, one is titled Liliastrum Alpinum majus, and the other Liliastrum Alpinum minus by Tournefort; the first of these rises with a flower-stalk more than a foot and a half high; the flowers are much larger, and there is a greater number upon each stalk than the second; but as there is no other essential difference between them, I have not put them down as different species; but the first is by much the finer plant, though not common in England, for the second sort is what I have always observed in the gardens here. I received some roots of the second sort from Mons. Richard, gardener to the King of France, which continue their difference in the same soil and situation with the first, which flowers earlier in the year; the leaves of this sort are somewhat like those of the Spiderwort, are pretty firm, and grow upright; the flower-stalks grow about a foot and a half high, and have several white flowers at the top, shaped like those of the Lily, which hang on one side, and have an agreeable scent; these are but of short duration, seldom continuing in beauty above three or four days; but when the plants are strong, they will produce eight or ten flowers upon each stalk, so they make a good appearance while they last.

This sort is usually propagated by parting the roots; autumn is the best season for doing this work, as it also is for transplanting the roots; for when they are removed in the spring, they seldom flower the same year, or if they do, it is but weakly: these plants should not be transplanted oftener than every third year, when the roots may be parted to make an increase of the plants, but they should not be divided too small; for if they are, it will be two years before they flower: these plants delight in a light loamy soil and in an open exposure, so must not be planted under the drip of trees; but if they are planted to an east aspect, where they may be protected from the sun in the heat of the day, they will continue in beauty longer than when they are more exposed.

HEMIONITIS [*Ημιονίτις*, of *Ημίονος*, a Mule, q. d. Mulewort, because this plant was believed to be as barren as a mule.] Moonfern.

This

This is a plant which is seldom propagated in gardens, therefore I shall not trouble the reader with any account of it more than this. That whoever hath a mind to cultivate any of the sorts, must procure the plants from the countries where they naturally grow; there are two sorts which are natives of the warmer parts of Europe, but in America there is a great number of very different kinds; these must be planted in pots filled with loamy undunged earth, and such of them as are natives of hot countries, must be placed in the stove; the others may be sheltered under a common frame in winter, and during the summer they must be frequently watered, but in winter they will require but little. In summer they should also have plenty of free air admitted to them; with this management the plants will thrive.

HEPATIC A. Boerh. Ind. Plant. Ranunculus. Tourn. Inst. R. H. 286. Anemone. Lin. Gen. Plant. 614. [*Ἡπατῖς*, of *ἥπαρ*, the liver, so called, because the leaves of this plant are divided into lobes, like the liver (but it does not at all take its name from its use, for it is of no virtue against the diseases of the liver, as many have erroneously imagined;) and trifolia, from its similitude thereto.] Hepatica, or Noble Liverwort.

The CHARACTERS are,

The flower hath a three-leaved empalement. It hath six petals, which are oval, and expand to the bottom, with a great number of slender stamina shorter than the petals, terminated by obtuse summits; and several germen collected into a head, supporting acuminate styles, crowned by obtuse stigmas. The germen afterward turns to acuminate seeds sitting round the styles.

This genus of plants is by Tournefort ranged among the Crowfoots, and by Linnæus it is placed under Anemone; but as the flowers of Anemone have no empalement, and the Hepatica hath a three-leaved one, it may be separated from that genus; and as it is well known in the gardens by this title, so should we range it with the Anemone, it might occasion confusion. This is ranged in the seventh section of Linnæus's thirteenth class, which includes the herbs with flowers having many stamina and styles.

The VARIETIES of this plant are,

1. **HEPATIC A** (*Nobilis*) trifolia, cœruleo flore. Clus. *The single blue Hepatica, or Noble Liverwort.*
2. **HEPATIC A** (*Plena*) trifolia cœruleo pleno. Clus. *The double blue Hepatica, or Noble Liverwort.*
3. **HEPATIC A** (*Alba*) trifolia, flore alba simplici. Boerh. Ind. *The single white Hepatica, or Noble Liverwort.*
4. **HEPATIC A** (*Vulgaris*) trifolia, rubro flore. Clus. *Single red Hepatica, or Noble Liverwort.*
5. **HEPATIC A** (*Rubra*) trifolia, flore rubro pleno. Boerh. Ind. *Double red, or Peach-coloured Hepatica.*

These plants are some of the greatest beauties of the spring; the flowers are produced in February and March in great plenty, before the green leaves appear, and make a very beautiful figure in the borders of the pleasure-garden, especially the double sorts, which commonly continue a fortnight long in flower than the single kinds, and the flowers are much fairer. I have seen the double white kind often mentioned in books, but could never see it growing, though I do not know but such a flower might be obtained from seeds of the single white, or blue kinds. I have sometimes known the double blue sort produce some flowers in autumn, which were inclining to white, and thereby some people have been deceived, who have procured the roots at that season, and planted them in their gardens; but the spring following their flowers were blue, as before; and this is what frequently happens, when the autumn is so mild as to cause them to flower; but whether the double white sort, mentioned in the books, was only this accidental alteration in the colour of the flower, I cannot say, though it seems very probable it was, since I never could hear of any person who ever saw the double white sort flower in the spring.

The single sorts produce seeds every year, whereby

they are easily propagated, and also new flowers may be that way obtained. The best season for sowing of the seeds is in the beginning of August, either in pots or boxes of light earth, which should be placed so as to have only the morning sun until October, when they should be removed into the full sun, to remain during the winter season; but in March, when the young plants will begin to appear, they must be removed again to a shady situation, and in dry weather should be frequently watered, and about the beginning of August they will be fit to be transplanted; at which time you should prepare a border facing the east, of good, fresh, loamy earth, into which you should remove the plants, placing them about six inches distance each way, closing the earth pretty fast to their roots, to prevent the worms from drawing them out of the ground, which they are very apt to do at that season; and, in the spring following, they will begin to shew their flowers; but it will be three years before they flower strong, and till then you cannot judge of their goodness; when, if you find any double flowers, or any of a different colour from the common sorts, they should be taken up, and transplanted into the borders of the flower-garden, where they should continue at least two years before they are taken up or parted; for it is remarkable in this plant, that where they are often removed and parted, they are very subject to die; whereas, when they are permitted to remain undisturbed for many years, they will thrive exceedingly, and become very large roots.

The double flowers, which never produce seeds, are propagated by parting their roots, which should be done in March, at the time when they are in flower; but you should be careful not to separate them into very small heads, nor should they be parted oftener than every third or fourth year, if you intend to have them thrive, for the reason before given. They delight in a strong loamy soil, and in an eastern position, where they may have only the morning sun, though they will grow in almost any aspect, not too warm, and are never injured by cold.

HEPATORIUM. See **EUPATORIUM.**

HEPTAPHYLLUM. See **POTENTILLA.**

HERACLEUM. Lin. Gen. 345. Sphondylium. Tourn. Inst. 1. Cow Parsnep.

The CHARACTERS are,

The calyx of the greater umbel is large, composed of many smaller, which are plain; the general involucre is composed of many leaves which fall off; the partial umbels have involucrems of three to seven leaves, the outer being the longest. The general umbel is deformed, the florets are mostly fruitful; those of the disk have five equal petals, which are inflexed; those of the rays have the same number of unequal petals, the outer being the largest; they have each five stamina longer than the petals, terminated by small summits. The germen is situated under the flower, and is almost oval, supporting two styles, crowned by simple stigmas. The germen afterward becomes an elliptical fruit, composed of two oval compressed seeds.

This genus of plants is ranged in the second order of Linnæus's fifth class, intitled Pentandria Digynia, the flowers having five stamina and two styles.

The SPECIES are,

1. **HERACLEUM** (*Sphondylium*) foliolis pinnatifidis. Hort. Cliff. 103. *Cow Parsnep with wing-pointed leaves.* Sphondylium vulgare hirsutum. C. B. P. 157. *Common Cow Parsnep.*
2. **HERACLEUM** (*Panaces*) foliis pinnatis, foliolis quinis, intermediis sessilibus, floribus radiatis. Hort. Upsal. 65. *Cow Parsnep with winged leaves having five lobes, and radiated flowers.* Panax Sphondylii folio, sc. Heracleum, C. B. P. 157.
3. **HERACLEUM** (*Alpinum*) foliis simplicibus, floribus radiatis. Lin. Sp. 359. *Cow Parsnep with simple leaves and radiated flowers.* Sphondylium Alpinum glabrum. C. B. P. 157. *Smooth Alpine Cow Parsnep.*
4. **HERACLEUM** (*Sibiricum*) foliis pinnatis, foliolis quinis, intermediis sessilibus, corollulis uniformibus. Hort. Upsal. 65. *Cow Parsnep with winged leaves, having five lobes*

lobes and a uniform corolla. *Pastinaca foliis simpliciter pinnatis, foliolis pinnatifidis.* Flor. Siber. i. p. 218.

The first sort grows naturally in most parts of England, so is rarely admitted into gardens; there is a variety (if not a distinct species of this) with narrower leaves, which are more divided than those of the first; however, as they are seldom cultivated, I shall not trouble the reader with their description.

The second sort is placed in most of the Pharmacopœias as a medicinal plant, but is rarely used as such, especially in England. This rises with a tall stalk near six feet high, which is embraced by the base of the leaves; these are winged, having generally five roundish lobes, whose surface is rough, of a dark green colour: the flowers are produced at the top of the stalks, being closely inclosed by the empalement when they first appear; but this afterward bursting, the umbel expands, having large petals on their exterior row, which are almost heart-shaped, and are succeeded by flat compressed seeds like those of Parsnep, but larger, having black streaks on their outside. This grows naturally on the Appenines.

The third sort grows naturally on the Alps, as also in Siberia: the stalks of this rise as high as those of the former, but the leaves are smooth. This is seldom cultivated.

The fourth sort grows naturally in Siberia and Transylvania; in the former country, the inhabitants eat the stalks and leaves of the plant for want of better food.

As these plants are rarely cultivated, unless in botanic gardens, so I shall recommend to those who are desirous to propagate either of the species, to sow their seeds in the autumn; and in the spring, when the plants are up, to hough the ground, cutting up the seeds, and thinning of the plants, in the same manner as is directed for Parsneps, with which culture the plants will thrive.

HERBA GERARDI. See **ANGELICA SYLVESTRIS MINOR.**

HERBALIST, HERBARIST, a person who is skilled in distinguishing the kinds, natures, or virtues of herbs or plants.

HERBA PARIS. See **PARIS.**

To **HERBARIZE**, to go abroad in the fields in quest of different or new herbs or plants.

HERBIFEROUS signifies bearing or bringing forth herbs.

HERBIVOROUS, i. e. devouring or feeding on herbs or Grass.

HERBOSE, grassy, or full of Grass or herbs.

HERBOSITY, grassiness, or abundance of Grass or herbs.

HERBULENT, grassy, full of Grass or herbs.

HERMANNIA. Tourn. Inst. R. H. 656. tab. 432.

Lin. Gen. Plant. 742. The title of this genus was given by Dr. Tournefort in honour of that great botanist, Paul Herman, M. D. Professor of Botany at Leyden.

The **CHARACTERS** are,

The flower hath a pitcher-shaped permanent empalement, divided into five parts at the brim. It hath five petals, which are narrow at their base, and twist against the sun within the tubulous empalement, but spread open above, where they are broad and obtuse. It hath five broad stamina, which are joined in one body, terminated by pointed summits, which are joined. In the center is situated a roundish five-cornered germen, supporting an awl-shaped style which is longer than the stamina, crowned by a single stigma. The germen afterward becomes a five-cornered roundish capsule, with five cells opening at the top, inclosing many seeds.

This genus of plants is ranged in the first section of Linnæus's sixteenth class, which includes the plants whose flowers have five stamina joined in one body to the style.

The **SPECIES** are,

1. **HERMANNIA** (*Alnifolia*) foliis cuneiformibus plicatis, crenato-emarginatis. Hort. Cliff. 342. *Herman-*

nia with wedge-shaped folded leaves, which are crenated and indented. *Hermannia frutescens, folio oblongo ferrato latiori.* Boerh. Ind. *Shrubby Hermannia with a broader, oblong, serrated leaf.*

2. **HERMANNIA** (*Grossulariæfolia*) foliis obovatis acutè incisis, pedunculis bifloris. Prod. Leyd. 347. *Hermannia with oval leaves acutely cut, and foot-stalks bearing two flowers.* *Hermannia frutescens folio grossulariæ parvo hirsuto.* Boerh. Ind. *Shrubby Hermannia with a small, hairy, Gooseberry leaf.*

3. **HERMANNIA** (*Althææfolia*) foliis obovatis plicatis crenatis tomentosis Hort. Cliff. 343. *Hermannia with oval, folded, woolly leaves, which are crenated.* *Hermannia frutescens, folio ibisci hirsuto molli, caule piloso.* Boerh. Ind. *Shrubby Hermannia with a soft, hairy, Marshmallow leaf, and woolly stalk.*

4. **HERMANNIA** (*Hyssopifolia*) foliis lanceolatis obtusis ferratis. Hort. Cliff. 342. *Hermannia with obtuse spear-shaped leaves, which are sawed.* *Hermannia frutescens, folio oblongo ferrato.* Tourn. *Shrubby Hermannia with an oblong serrated leaf.*

5. **HERMANNIA** (*Trifoliato*) foliis oblongo-ovatis crenatis tomentosis flore mutabili. *Hermannia with oblong, oval, crenated woolly leaves, and a changeable flower.* *Hermannia frutescens, folio oblongo molli cordato hirsuto.* Boerh. Ind. *Shrubby Hermannia with a soft, oblong, hairy, heart-shaped leaf.*

6. **HERMANNIA** (*Pinnata*) foliis tripartitis, media pinnatifida. Hort. Cliff. *Hermannia with tripartite leaves ending in many points.* *Hermannia frutescens, folio multifido tenui, caule rubro.* Boerh. Ind. alt. *Shrubby Hermannia with a narrow multifid leaf, and a red stalk.*

7. **HERMANNIA** (*Lavendulifolia*) foliis lanceolatis obtusis integerrimis. Hort. Cliff. 342. *Hermannia with obtuse spear-shaped leaves, which are entire.* *Hermannia frutescens, folio lavendulæ latiori & obtuso, flore parvo aureo.* Boerh. Ind. alt. *Shrubby Hermannia with a broad, blunt, Lavender leaf, and a small golden flower.*

8. **HERMANNIA** (*Hirsuta*) foliis simplicibus ternatisque hirsutis sessilibus. *Hermannia with single and trifoliate leaves which are hairy, and sit close to the stalk.*

The first sort rises with a shrubby stalk six or eight feet high, dividing into many erect irregular branches, covered with a brown bark, garnished with wedge-shaped leaves, which are narrow at their base, but broad and round at the top; they are about an inch long, and three quarters broad at the point, where they are indented and crenated. The flowers are produced in short spikes on the upper part of the branches; they are of a pale yellow colour, but small; these appear in April and May, and are often succeeded by seeds, which ripen in August.

The second sort is a shrub of lower stature than the first, but sends out a great number of branches, which spread wide on every side, garnished with smaller leaves than those of the former, which are rough, and sit close to the branches. The flowers are produced in short close spikes at the end of every shoot, so that the whole shrub seems covered with flowers; they are of a bright yellow, and appear toward the end of April, but are not succeeded by seeds in England.

The third sort is a plant of humbler growth than either of the former, seldom rising more than two feet and a half high; the stem is not so woody, and the branches are soft and slender, garnished with oval woolly leaves, which are plaited and crenated on the edges; the flowers are produced in loose panicles at the end of the branches; they are larger than those of the other species, and have very hairy empalements. This sort flowers in June and July, and frequently puts out more in the autumn.

The fourth sort has been longer in the European gardens than either of the other. This rises with a shrubby upright stalk to the height of seven or eight feet, sending out many ligneous branches from the side, which also grow more erect than any of the other; these are clothed with obtuse spear-shaped leaves,

about an inch and a half long, and half an inch broad, sawed on the edges toward the end: the flowers come out in small bunches from the side of the stalk; they are of a pale Straw colour, and appear in May and June; these are frequently succeeded by seeds, which ripen the latter part of August.

The fifth sort seldom rises more than two feet high, with a soft ligneous stalk, sending out slender irregular branches, garnished with oblong, oval, woolly leaves, standing upon pretty long footstalks; the flowers are produced in loose spikes at the end of the branches; these are, at their first appearance, of a gold colour, but after they have been some days open, they change to yellow. This flowers in June and July.

The sixth sort rises with a shrubby stalk near three feet high, sending out many slender branches, covered with a reddish bark, garnished with narrow wing-pointed leaves; the flowers come out from the side of the branches in small clusters; they are small, and of a deep yellow colour. This flowers in June and July.

The seventh sort hath shrubby branching stalks, which are very bushy, but seldom rise more than a foot and a half high; the branches are very slender, and garnished with hairy, pale, green leaves of different sizes; some of them are two inches long, and one broad at their ends; but their common size is seldom more than one inch long, and half an inch broad at their points; they are entire, and sit pretty close to the branches; the flowers come out from the side of the stalk singly, they are small, and of a yellow colour. This sort flowers most part of summer.

The eighth sort I raised from seeds which came from the Cape of Good Hope. This rises with a shrubby hairy stalk about two feet high, sending out many side branches, which grow more erect than those of the former, garnished with oblong, veined, hairy leaves, which are sometimes single, and at other times come out by threes, the middle one being the largest; the flowers are produced toward the end of the branches; they are large, and of a deep yellow colour, with large, swollen, hairy empalements. This sort continues flowering most part of summer.

All the species of this genus yet known, are natives of the country about the Cape of Good Hope, from whence most of them were brought to the gardens in Holland, where they have been propagated and spread through most parts of Europe.

The plants are all propagated by planting cuttings of them during any of the summer months, in a bed of fresh earth, observing to water and shade them until they are well rooted, which will be in about six weeks after planting; then you should take them up, preserving a ball of earth to their roots, and plant them into pots filled with light fresh earth, placing them in a shady situation until they have taken fresh root; after which they may be exposed to the open air, with Myrtles, Geraniums, &c. until the middle or latter end of October, when they must be removed into the green-house, observing to place them in the coolest part of the house, where they may have as much free air as possible; for if they are too much drawn in the house, they will appear very faint and sickly, and seldom produce many flowers; whereas, when they are only preserved from the frost, and have a great share of free air, they will appear strong and healthy, and produce large quantities of flowers in April and May, during which season they make a very handsome appearance in the green-house: they must also be frequently watered, and will require to be new-potted at least twice every year, i. e. in May and September; otherwise their roots will be so matted, as to prevent their growth.

These plants rarely produce good seeds with us, except the fourth and eighth sorts, which ripen their seeds every year in England; the other rarely producing any, I suppose this may be accounted for by their having been long propagated from cuttings; for those plants which I have raised from seeds, have been fruitful two or three years after, but I have always

found those plants which have been propagated by cuttings taken from these, have soon become barren: the same thing I have observed in many other plants, therefore those who are desirous to continue their plants fruitful, should constantly raise them from seeds. These, as also those which are obtained from abroad, must be sown upon a moderate hot-bed; and when the plants come up, they must be transplanted into small pots, and plunged into another very moderate hot-bed, in order to promote their rooting; after which they must be hardened by degrees, to endure the open air in summer, and may then be treated as the old plants.

HERMODACTYLUS, the Hermodactyl, commonly called Snake's-head Iris.

This genus is by Dr. Linnæus joined to Iris, the characters of the flower agreeing pretty well with those of that genus; from which Tournefort has separated it from the difference of the root, which is not according to his own system, where he makes the shape of the petals with their number and position, the principal characteristics in distinguishing the classes and genera; but as this plant requires a particular treatment, so I have continued it under Tournefort's title.

The CHARACTERS are,

It hath a Lily-shaped flower, consisting of one leaf, and shaped exactly like an Iris, but has a tuberos root, divided into two or three dug, like oblong bulbs.

We have but one SPECIES of this plant, viz.

HERMODACTYLUS (*Tuberosa*) folio quadrangulo. C. B. P. *Snake's head Iris*, vulgò. This is also called *Iris tuberosa* Beigarin, i. e. *Tuberos Iris of the Dutch*.

This plant is easily propagated by its tubers, which should be taken off soon after the green leaves decay, which is the proper season for transplanting the root; but they should not be kept long out of the ground, lest they shrink, which will cause them to rot when they are planted. They should have a loamy soil, not too strong nor deep, and must be planted to an east aspect, where they will flower very well. The roots should not be removed oftener than once in three years, if you design to increase them; but then they should be planted at a farther distance from each other, than if they were to remain but one year; and the beds should be kept clear from weeds, and at Michaelmas there should be some fine earth laid over the beds, which will greatly strengthen their roots. The distance which these plants should be allowed is six inches square, and they should be placed three inches deep in the ground. These produce their flowers in May, and their seeds are ripe in August; but as they multiply pretty fast by their roots, few people are at the trouble of raising them from seeds; but those who have an inclination so to do, must treat them in the manner directed for the bulbous Irises.

The roots of this plant are very apt to run deep into the ground, and then they seldom produce flowers; and many times they shoot so deep as to be lost, especially where the soil is very light; therefore to prevent this, it will be proper to lay a thickness of rubbish under the border where these are planted, to hinder them from getting down. This should always be practised in light ground, but in strong land there will be no occasion to make use of this precaution, because they do not shoot downward so freely in that.

This plant has by some botanic writers been supposed the true Hermodactyl, but what has been long used in Europe for that is the root of a Colchicum.

HERNANDIA. Plum. Nov. Gen. 8. tab. 40. Lin. Gen. Plant. 931. Jack-in-a-Box, vulgò.

The CHARACTERS are,

It hath male and female flowers on the same plant; the male flowers have a partial involucre, composed of four oval small leaves, which inclose three flowers; each of these has a proper bell-shaped empalement of one leaf; the petal is funnel-shaped, cut into six segments at the brim; it hath three short stamina inserted in the empalement, terminated by erect summits. The female flowers are

are shaped like the male, but want stamina; they have a roundish germen, supporting three slender styles, crowned by acute stigmas. The empalement afterward becomes a large, swollen, oblong fruit, perforated at each end, inclosing one hard globular nut.

This genus of plants is ranged in the third section of Linnæus's twenty-fifth class, intitled Monœcia Triandria, which includes those plants which have male and female flowers in the same plant, whose male flowers have three stamina.

We have but one SPECIES of this genus in England, viz.

HERNANDIA (*Sonora*) foliis peltatis. Hort. Cliff. 485. tab. 13. *Hernandia* amplo hederæ folio umbilicato. Plum. *Hernandia* with a large umbilicated Ivy leaf, commonly called in the West-Indies, *Jack-in-a-box*.

This plant is very common in Jamaica, Barbadoes, St. Christopher's, and many other islands in the West-Indies, where it is known by the name of *Jack-in-a-box*. The fruit of this plant when ripe, is perforated, and the nut in the inside becomes hard; so that when the wind blows through the fruit, it makes a whistling noise, which may be heard at a distance; from whence, I suppose, the inhabitants gave this name to the plant. It grows in the gullies, where there are rills of water.

In Europe this plant is preserved in curious gardens, with other tender exotic plants. It is propagated by sowing the seeds in a hot-bed in the spring; and when the plants have arisen two inches high, they should be transplanted each into a separate pot, filled with fresh rich earth, and plunged into the hot-bed again, observing to water and shade them until they have taken root; after which time they must have air admitted to them, (by raising the glasses) in proportion to the warmth of the air, or the heat of the bed in which they are placed; and should be frequently watered, otherwise they will not thrive. As the plants advance, they should be removed into larger pots, which should be filled with rich earth; but in doing this, you should be very careful not to break the roots, as also to preserve a good ball of earth to them; and if their leaves should hang after being removed, the plants must be screened from the sun until they have taken new root. The best time to shift these plants is in July, that they may be well rooted before the cold approaches; the plants must be constantly kept in the bark-stove: in winter they should have a moderate share of heat, and in the summer they must have plenty of air in hot weather. With this management, the plants will grow to the height of sixteen feet or more, and the leaves being very large, will make a beautiful appearance in the stove. It hath not as yet flowered in England, though we may expect some of the large plants to flower in a short time.

HERNIARIA. Tourn. Inst. R. H. 507. tab. 228. Lin. Gen. Plant. 272. [of *Hernia*, Lat. a rupture.] *Rupturewort*.

The CHARACTERS are,

The flower hath no petals, but a coloured empalement of one leaf, cut into five parts which spread open. It hath five small awl-shaped stamina, situated in the divisions of the empalement, terminated by single summits, and five others which are barren, placed alternately between them. In the center is an oval germen with two stigmas, which have acute points; the germen afterward turns to a small capsule inclosed in the empalement, having one oval-pointed seed.

This genus of plants is ranged in the second section of Linnæus's fifth class, intitled Pentandria Digynia, which includes the plants whose flowers have five stamina and two styles.

The SPECIES are,

1. **HERNIARIA** (*Glabra*) glabra herbacea. J. B. 3. 378. *Smooth Rupturewort*.
2. **HERNIARIA** (*Hirsuta*) hirsuta herbacea. J. B. 3. 379. *Rough or hairy Rupturewort*.
3. **HERNIARIA** (*Alfines folia*) alfinæ folio. Tourn. Inst. 507. *Rupturewort with a Chickweed leaf*.

4. **HERNIARIA** (*Fruticosa*) caulibus fruticosis, floribus quadrifidis. Amoen. Acad. 4. p. 369. *Rupturewort with ligneous stalks and quadrifid flowers*. *Herniaria fruticosa*, viticulis lignosis. C. B. P. 382.

The two first sorts grow naturally in England, but not very common; they are low trailing plants, their branches lying on the ground, and extend seven or eight inches each way; they have leaves like the smaller Chickweed, the first is smooth, and those of the second are hairy; the flowers come out in clusters from the side of the stalks at the joints; they are small, and of a yellowish green, so make no appearance.

The fourth sort hath shrubby stalks which trail upon the ground, garnished with small hairy leaves like the second sort; the flowers are also very like that.

The third sort is an annual plant, which grows naturally in France and Italy. This doth not spread so much as either of the other sorts, but the flowers and leaves are somewhat like the first, but larger.

These plants are seldom cultivated, but in botanic gardens for the sake of variety. The three first are annual plants, seldom continuing longer than one year; and must be permitted to shed their seeds, whereby they are better preserved than if sown with art. The fourth sort is an abiding plant, which may be propagated by cuttings; but as they are plants of no beauty, they are rarely preserved in gardens.

The first sort is what should be used in the shops, but is rarely seen in London, the herb-women commonly bringing the Parsley Breakstone to the markets, which is sold instead of this plant.

HESPERIS. Tourn. Inst. R. H. 222. tab. 108. Lin. Gen. Plant. 731. [some derive the name of this plant from Hesperia, Italy, from whence the people were anciently called Hesperides; but it is pretty plain, that the name was taken from *Hesperis*, because the flower commonly smells most in an evening; either of these may be admitted. It is called *Viola Matronalis*, because it resembles the Violet, and was at first cultivated by women.] *Dame's Violet*, *Rocket*, or *Queen's Gilliflower*; in French, *Juliane*, or *Julienne*.

The CHARACTERS are,

The flower is composed of four oblong petals in form of a cross, whose base or tails are narrow, and are situated in a four-leaved empalement, which falls away. It hath six awl-shaped stamina, four of them as long as the tube of the flower, and two much shorter, terminated by narrow erect summits, reflexed at their points. It hath a honey-gland situated between the two short stamina, and a four-cornered germen the length of the stamina, but no style, the oblong erect stigma sitting on the germen; the stigma is divided into two parts, which join at their points. The germen afterward becomes a plain, long, compressed pod with two cells, divided by an intermediate partition, inclosing many oval compressed seeds.

This genus of plants is ranged in the second section of Linnæus's fifteenth class, intitled Tetradinamia Siliquosa, the flowers having four long and two short stamina, and are succeeded by long pods.

The SPECIES are,

1. **HESPERIS** (*Matronalis*) caule simplici erecto, foliis ovato-lanceolatis denticulatis, petalis mucrone emarginatis. Lin. Sp. 927. *Dame's Violet with a single erect stalk, oval, spear-shaped, indented leaves, and the petals of the flowers indented at the top*. *Hesperis hortensis*, flore purpureo. C. B. P. 202. *Garden Rocket with a purple flower*.
2. **HESPERIS** (*Alba*) caule simplici erecto, foliis lanceolatis serratis, petalis integris. *Dame's Violet with a single upright stalk, spear-shaped sawed leaves, and the petals of the flower entire*. *Hesperis hortensis* flore candido. C. B. P. 202. *Garden Rocket with a white flower*.
3. **HESPERIS** (*Inodora*) caule simplici erecto, foliis subhastatis dentatis petalis obtusis. Lin. Sp. 727. *Dame's Violet with a single upright stalk, halbert-shaped, indented, obtuse leaves and petals*. *Hesperis sylvestris inodora*. C. B. P. 202. *Unsavory wild Rocket*.

4. **HES-**

4. *HESPERIS (Tristis)* caule hispido ramoso patente. Hort. Upsal. 187. *Dame's Violet with a prickly, branching, spreading stalk.* *Hesperis montana*, pallidia, odoratissima. C. B. P. 202. *Sweetest pale Mountain Rocket.*
5. *HESPERIS (Siberica)* caule simplici, foliis lanceolatis dentato-ferratis, petalis obtusissimis integris. Lin. Sp. 927. *Dame's Violet with a single stalk, spear-shaped sawed leaves, and blunt entire petals to the flower.*
6. *HESPERIS (Exigua)* caule ramosissimo diffuso, foliis lineari-lanceolatis dentatis, siliquis apice truncatis. *Dame's Violet with a very branching diffused stalk, narrow, spear-shaped, indented leaves, and the points of the pods shaped like a truncheon.* *Hesperis exigua lutea*, folio dentato angusto. Boerh. Ind. 146. *Rocket with a very small yellow flower, and a narrow indented leaf.*
7. *HESPERIS (Dentata)* foliis dentato-pinnatifidis, caule laevi. Lin. Sp. Plant. 664. *Dame's Violet with wing-pointed indented leaves, and a smooth stalk.* *Hesperis flore albo minimo*, siliquâ longâ, folio profundè dentato. Boerh. Ind. alt. 2. 20. *Rocket with a small white flower, a long pod, and leaves deeply indented.*
8. *HESPERIS (Africana)* caule ramosissimo diffuso, foliis petiolatis lanceolatis acute dentatis scabris siliquis sessilibus. Lin. Sp. Plant. 928. *Dame's Violet with very branching diffused stalks, spear-shaped, rough, sawed leaves, and pods sitting close to the stalks.* *Hesperis Africana*, hieracii folio hirsuto, flore minimo purpurascens. Nissol. Act. *African Rocket with a hairy Hawkweed leaf, and a very small purplish flower.*
9. *HESPERIS (Verna)* caule erecto ramoso, foliis cordatis amplexicaulibus serratis villosis. Lin. Sp. Plant. 664. *Dame's Violet with an erect branching stalk, and hairy, sawed, heart-shaped leaves embracing the stalk.* *Turritis annua verna*, purpurascens flore. Tourn. Inst. 224. *Annual vernal Tower Mustard, with a purplish flower.*

The first sort grows naturally in Italy; this was formerly in greater plenty in the English gardens than at present, having been long neglected because the flowers were single, and made but little appearance; however, as the flowers have a very grateful scent, so the plant is worthy of a place in every good garden. This rises with an upright stalk a foot and a half high, garnished with spear-shaped leaves which sit close to the stalk, and are slightly indented on their edges, ending in acute points: the flowers are produced in a loose thyrse on the top of the stalks; they are composed of four petals, which are roundish and indented at their points, of a deep purple colour, and smell very sweet, especially in the evening or in cloudy weather. It flowers in June, and the seeds ripen the latter end of August. It is a biennial plant, so that young plants should be raised every year, to supply the place of those which decay: if the seeds are permitted to scatter, the plants will come up without trouble in the spring; and if the seeds are sown, the best season for it is in the autumn; because those which are sown in the spring often fail if the season proves dry, or will remain a long time in the ground before they vegetate. This plant should have a loamy undunged soil, in which it will thrive better than in rich land.

There is a variety of this with double flowers, in some of the gardens in France; but that which we have in England, is a variety of the third sort with unfavoury flowers.

The second sort has been generally supposed only a variety of the first, differing in the colour of the flower, but is certainly a distinct species; the leaves of this are not so long, but much broader than those of the first, and their borders are entire; the flowers are not quite so large, nor do they form so good spikes; they are white, and have not so fine a scent as the first. This is also a biennial plant, requiring the same treatment as the first.

The third sort grows naturally in Hungary and Austria. This rises with an upright stalk near two feet high, garnished with spear-shaped leaves, ending in acute points, and sharply indented on their edges; they are of a dark green, and sit close to the stalks;

the flowers grow in loose spikes on the top of the stalks; in some they are white, in others purple, and sometimes both colours striped in the same flower; these have no odour, so are not deserving of a place in gardens, but may be propagated in the same manner as the two former.

From this sort, the double white and purple Rockets have been accidentally obtained, which are much esteemed for the beauty of their flowers; and if they had the agreeable odour of the Garden Rocket, they would be some of the best furniture for the borders of the flower-garden, but they are without scent; however, for the beauty of their flowers, they are by some greatly esteemed, therefore I shall here insert the best method of propagating them yet known.

These plants are naturally biennial, so the plants with single flowers rarely survive the second year; nor will those with double flowers continue much longer; so that unless young plants are annually raised to supply the place of the old ones, there will soon be a want of them, which is what few persons are careful enough to observe; but thinking the roots to be perennial, trust to their putting out offsets, or the plants remaining after they have flowered; and finding them decay, are apt to think their soil very improper for them, and are at a loss to account for their decaying; whereas, when the plants have flowered, they have finished their period, and seldom continue to flower a second time from the same root; though in poor land, they will often put out a few weak offsets, which may flower again, but seldom so strong as the principal roots; therefore those who are desirous to propagate these plants, should do it in the following manner:

There should be some strong roots of each sort kept apart for this purpose, which are not intended to flower; when these have shot up their flower-stalks about six inches high, they should be cut close to the bottom; each of these may be divided in the middle to make two cuttings, which should be planted in a soft, gentle, loamy soil, to an east exposure, where they may have only the morning sun; and these may be planted pretty near together, so as to be covered with hand or bell-glasses, which should be put over them after the cuttings have been well watered, and closely shut down, drawing the earth round the rim of the glasses to exclude the air; then the glasses should be shaded with mats every day when the sun is hot; and if the cuttings are gently refreshed with water once in seven or eight days, it will be sufficient, for too much moisture will cause them to rot: when these are watered, the glasses should be closely shut down again as before; with this management the cuttings will put out roots in five or six weeks, and will begin to shoot above; then the glasses should be gently raised on one side to admit the air to them, and so gradually harden them to the open air, to prevent their drawing up weak. When these have made good roots, they should be carefully removed, and planted in an east border at about eight or nine inches asunder, observing to shade and water them till they have taken new root; after which they will require no other care, but to keep them clean from weeds till the autumn, when they may be transplanted into the borders of the pleasure-garden, where they are designed to flower.

The roots which are thus cut down, will send up more stalks than before; and when these are of a proper height, they may be cut off and treated in the same way; so that if the roots are sound, there may be two or three crops of these cuttings taken from them, and by so doing, the old roots may be continued much longer than if they are permitted to flower; and by this management, there may be always a supply of good plants for the flower-garden.

These plants are very subject to canker and rot when they are planted in a light rich soil, but in poor strong ground, I have seen them thrive and flower in the utmost perfection, where the stems of flowers have been as large, and the flowers as fair as the finest double

Stock-

H E L

Stock-gillflowers. Their season of flowering is in the beginning of June, and I have frequently raised young plants from the stalks after the flowers have decayed, by cutting them in lengths, and planting them in the manner before directed; but these seldom make so good plants as the young cuttings, nor are they so certain to grow, therefore the other are to be preferred.

The fourth sort grows naturally in Hungary. This is much cultivated in the gardens abroad, for the great fragrantcy of its flowers, which in the evening is so strong, as to perfume the air at a great distance, especially where there are any number of the plants. The ladies in Germany are very fond of this plant, and during the season of their flowering, have the pots placed in their apartments every evening, that they may enjoy the fragrantcy of their flowers; for they have but little beauty, being smaller than those of the Garden Rocket, and of a pale colour, but the scent of their flowers is much preferable to them; though in the day-time, if the weather is clear, they have very little odour; but when the sun leaves them, their fragrantcy is expanded to a great distance. To this species it is supposed, that the title of Dame's Violet was first applied.

This sort is very rarely seen in the English gardens: I suppose it has been neglected, because the flowers make no appearance. It is a biennial plant like the Garden Rocket, which is propagated by seeds in the same manner; but the plants are not quite so hardy, and are very subject to rot in winter, especially on a moist soil, or in rich land, where they are apt to grow very rank, so are soon injured by wet and cold in the winter; therefore the plants of this sort should be planted in a dry poor soil, and a warm situation; and if some of them are planted in pots to be placed under a common frame in winter, where they may be sheltered from hard rains and frost, but enjoy the free air at all times when the weather is mild, it will be a sure way to preserve them.

The leaves of this sort are much larger than those of the Garden Rocket, and of a paler green; the stalks are closely set with bristly hairs; the flowers grow in loose panicles at the top of the stalk, and appear about the same time with the Garden Rocket.

The seeds of the fifth sort were sent me from Germany without any title, nor any account of the country from whence it came; but as it was sent with the seeds of some Siberian plants, I suppose this came from the same country. This is a biennial plant, which rises with a strong branching stalk between two and three feet high, which is very hairy, garnished with oblong heart-shaped leaves, ending in acute points, sitting close to the stalk; they are four inches long, and one and a half broad at their base, gradually diminishing to the point, and are slightly sawed on their edges; the upper part of the stalk divides into two or three branches, which are garnished with small leaves of the same shape with those below, and are terminated with loose panicles of single, large, purple flowers of great fragrantcy. This sort flowered the end of June 1757, but the great rains which fell in August, rotted the plants before the seeds were ripe.

The sixth sort grows naturally in the warm parts of Europe; this is annual; the stalks rise about eight or nine inches high, branching out greatly on every side in a confused order; they are garnished with small, narrow, indented leaves, and are terminated by clusters of small yellow flowers, which make no appearance.

The seventh sort grows naturally in Sicily. This is an annual plant, which seldom rises more than six inches high; the stalk branches toward the top into three or four smaller, which are terminated by small white flowers; the leaves are two inches long and one broad, cut almost to the midrib on each side, so as to resemble a winged leaf.

The eighth sort grows naturally in Africa. This is an annual plant with a very branching stalk, which rises about nine inches high, garnished with rough

H I B

spear-shaped leaves sawed on their edges, and terminated by loose panicles of small purple flowers, which appear in June and July; these are succeeded by long pods sitting close to the stalks, and are filled with small seeds which ripen in September.

These three sorts are rarely cultivated, except in botanic gardens for the sake of variety. If the seeds of these are permitted to scatter, the plants will come up without care, and only require to be kept clean from weeds; or they may be sown either in the spring or the autumn where they are to stand, for they do not bear transplanting well.

The ninth sort is an annual plant, which grows naturally in the south of France. This sends out several heart-shaped leaves from the root, which spread on the ground; they are sawed and hairy: the stalk rises nine inches high, branching toward the top, garnished with leaves of the same shape, which embrace the stalks with their base; the flowers are produced in loose panicles at the end of the branches; they are of a lively purple colour, and those plants which rise in the autumn, flower early in the spring. If these seeds are sown in the autumn, they succeed much better than in the spring.

HEUCHERA. Lin. Gen. Plant. 283. Sanicle.

The CHARACTERS are,

The flower is composed of five narrow petals, which are inserted in the border of the one-leaved empalement. It hath five erect awl-shaped stamina, which are much longer than the empalement, terminated by roundish summits. It hath a roundish bifid germen, with two erect styles the length of the stamina, crowned by obtuse stigmas. The germen afterward turns to an oval-pointed capsule with two horns, which are reflexed, having two cells filled with very small seeds.

This genus of plants is ranged in the second section of Linnæus's fifth class, which includes those plants whose flowers have five stamina and two styles.

We have but one SPECIES of this genus, viz.

HEUCHERA (*Americana*.) Hort. Cliff. 82. Mitella Americana, flore squallidè purpureo villosa. Boerh. Ind. alt. *Mitella of America, with hairy flowers of a dirty purple colour.*

This plant grows naturally in Virginia, but is hardy enough to thrive in the open air in England. It hath a perennial root, which sends out many heart-shaped oval leaves, which are indented into four or five lobes, and are crenated on their edges, of a lucid green, and smooth; from between these come out the foot-stalks of the flower, which are naked, and rise a foot high, dividing at the top into a loose panicle, sustaining many small hairy flowers, of an obsolete purple colour. This flowers in May, and the seeds ripen in August.

It is propagated by parting the roots in autumn, and should be planted in a shady situation; there is little beauty in this plant, but it is preserved in some gardens for the sake of variety.

HIBISCUS. Lin. Gen. Plant. 756. Ketmia. Tourn. Inst. R. H. 99. tab. 26. Syrian Mallow.

The CHARACTERS are,

The flower has a double empalement, which is permanent; the outer is composed of eight or ten narrow leaves, the inner is shaped like a cup, and is of one leaf, cut at the brim into five acute points. It hath five heart-shaped petals, which join at their base into one. It hath many stamina, which are joined to the style, in form of a column, within the tube of the flower, but expand toward the top, and are terminated by kidney-shaped summits. It has a round germen, with slender styles longer than the stamina, crowned by roundish stigmas. The germen afterward turns to a capsule with five cells, opening in five parts, inclosing kidney-shaped seeds.

This genus of plants is ranged in the third section of Linnæus's sixteenth class, which includes those plants whose flowers have many stamina joined to the styles in one body, forming a column.

The SPECIES are,

1. HIBISCUS (*Syriacus*) foliis cuneiformi-ovatis, supernè inciso-dentatis, caule arboreo. Hort. Cliff. 350. *Hibiscus*

cus with wedge-shaped oval leaves, whose upper parts are cut, indented, and a tree-like stalk. *Ketmia Syrorum* quibusdam. C. B. P. 316. The Syrian *Ketmia*, commonly called *Althæa frutex*.

2. *HIBISCUS* (*Sinensis*) foliis cordato-quinquangularis obsoletè ferratis, caule arboreo. Hort. Upsal. 205. *Hibiscus* with heart-shaped leaves, having five angles which are slightly sawed, and a tree-like stalk. *Ketmia sinensis*, fructu subrotundo. Tourn. Inst. R. H. 100. China *Ketmia* with a roundish fruit, commonly called China Rose.
3. *HIBISCUS* (*Abelmoschus*) foliis subpeltato-cordatis septemangularibus, ferratis hispidis. Hort. Cliff. 349. *Hibiscus* with heart-shaped target leaves, having seven angles which are sawed, and set with prickly hairs. *Ketmia Americana* hirsuta, flore flavo, & semine moschato. Tourn. Inst. R. H. 100. Hairy American *Ketmia* with a yellow flower and musky seed, commonly called Musk.
4. *HIBISCUS* (*Manihot*) foliis palmato-digitatis septempartitis. Hort. Cliff. 350. *Hibiscus* with fingered leaves, which are divided into seven parts. *Ketmia Americana*, folio Papayæ, flore magno flavescente, fundo purpureo, fructu erecto pyramidalis hexagono, semine rotundulo sapore fatuo. Boerh. Ind. alt. 1. 272. American *Ketmia* with a Papaw leaf, and a large yellow flower, having a purple bottom, a pyramidal, six-cornered, erect fruit, and round seeds of a flat taste.
5. *HIBISCUS* (*Tomentosus*) foliis cordatis angulatis ferratis tomentosis, caule arboreo. *Hibiscus* with angular, heart-shaped, sawed, woolly leaves, and a tree-like stalk. *Malva arboreo*, folio oblongo acuminato veluto dentato & leviter sinuato, flore ex rubro flavescente. Sloan. Cat. 95. Tree Mallow with oblong, acute-pointed, indented leaves, slightly sinuated, and a reddish-yellow flower.
6. *HIBISCUS* (*Tiliaceus*) foliis cordatis subrotundis indivisis acuminatis crenatis, caule arboreo. Prod. Leyd. 532. *Hibiscus* with entire heart-shaped leaves, and a tree-like stalk. *Ketmia Indica* tiliæ folio. Tourn. Inst. R. H. 100. Indian *Ketmia* with a Lime-tree leaf.
7. *HIBISCUS* (*Javanica*) foliis ovatis acuminatis ferratis glabris, caule arboreo. Flor. Zeyl. 260. *Hibiscus* with oval-pointed, sawed, smooth leaves, and a tree-like stalk. *Alcea Javanica* arborescens, flore pleno rubicundo. Bryen. Cent. 121. tab. 56. Tree Vervain Mallow of Java, with a double red flower, called in India Shoe-flower.
8. *HIBISCUS* (*Vitifolius*) foliis ferratis inferioribus ovatis indivisis, superioribus quinquepartitis, caule aculeato. Prod. Leyd. 358. *Hibiscus* with sawed leaves, the lower oval and undivided, the upper divided into five parts, and a prickly stalk. *Ketmia Indica* vitis folio, magno flore. Tourn. Inst. R. H. 100. Indian *Ketmia* with a Vine leaf and large flower.
9. *HIBISCUS* (*Sabdariffa*) foliis ferratis, inferioribus cordatis, mediis tripartitis, summis quinquepartitis, caule aculeato. *Hibiscus* with sawed leaves, the lower ones being heart-shaped, the middle divided into three parts, the upper into five, and a prickly stalk. *Ketmia Ægyptiaca* vitis folio, parvo flore. Tourn. Inst. R. H. 100. Egyptian *Ketmia* with a Vine leaf and a small flower.
10. *HIBISCUS* (*Gossypifolius*) foliis quinquelobatis ferratis, caule glabro. *Hibiscus* with sawed leaves divided into five lobes, and a smooth stalk. *Ketmia Indica*, *Gossypii* folio, acetosæ sapore. Tourn. Inst. R. H. 100. Indian *Ketmia* with a Cotton leaf, and the taste of Sorrel.
11. *HIBISCUS* (*Ficulneus*) foliis quinquefido-palmatis, caule aculeato. Hort. Cliff. 498. *Hibiscus* with hand-shaped five-pointed leaves, and a prickly stalk. *Ketmia Zeylanica*, fici folio, perianthio oblongo integro. Hort. Elth. 190. tab. 157. *Ketmia* of Ceylon with a Fig leaf, and an oblong entire perianthium.
12. *HIBISCUS* (*Surattensis*) foliis quinquepartitis, lobis ovato-lanceolatis hirsutis crenatis, caule spinosissimo. *Hibiscus* with leaves divided into five lobes, which are oval, spear-shaped, hairy, and crenated, and a very prickly stalk. *Ketmia Indica* aculeata, foliis digitatis. Tourn. Inst. 101. Prickly Indian *Ketmia* with hand-shaped leaves.

13. *HIBISCUS* (*Cordifolius*) foliis cordatis hirsutis crenatis, floribus lateralibus, caule arboreo ramoso. *Hibiscus* with heart-shaped, hairy, crenated leaves, flowers growing from the sides of the branches, and a tree-like branching stalk. *Ketmia Americana* frutescens foliis subrotundis crenatis hirsutis, flore luteo. Hoult. Shrubby American *Ketmia* with roundish, hairy, crenated leaves, and a yellow flower.
 14. *HIBISCUS* (*Babamensis*) foliis oblongo-cordatis glabris, denticulatis, subtus incanis, floribus amplissimis. *Hibiscus* with oblong, heart-shaped, smooth, indented leaves, hoary on their under side, and very large flowers.
 15. *HIBISCUS* (*Ficifolius*) foliis quinquepartito pedatis, calycibus inferioribus latere rumpentibus. Lin. Sp. Plant. 696. *Hibiscus* with leaves like a hand, divided into five parts, and the lower empalement torn sideways. *Ketmia Brasiliensis*, folio ficis, fructu pyramidato sulcato. Tourn. Inst. R. H. 100. *Ketmia* of the Brasils with a Fig leaf, and a pyramidal furrowed fruit.
 16. *HIBISCUS* (*Pentacarpus*) foliis inferioribus cordatis angulatis, superioribus subhastatis, floribus subnulantibus, pistillo cernuo. Lin. Sp. Plant. 697. *Hibiscus* with lower leaves heart-shaped and angular, the upper ones somewhat spear-shaped, nodding flowers, and a recurved pistil. *Ketmia palustris* minor, folio angusto, flore parvo purpurascens, fructu depresso pentagona. Zannich. Venet. 155. tab. 91. Smaller Marsh *Ketmia* with a narrow leaf, a small purplish flower, and a five-cornered depressed fruit.
 17. *HIBISCUS* (*Populneus*) foliis ovatis acuminatis ferratis, caule simplicissimo, petiolis floriferis. Hort. Upsal. 205. *Hibiscus* with oval-pointed sawed leaves, a single stalk, and foot-stalks having flowers. *Ketmia Africana* Populi folio. Tourn. Inst. 100. African *Ketmia* with a Poplar leaf.
 18. *HIBISCUS* (*Palustris*) caule herbaceo simplicissimo, foliis ovatis subtrilobis, subtus tomentosis, floribus axillaribus. Lin. Sp. Plant. 693. *Hibiscus* with a single herbaceous stalk, oval leaves having three lobes, woolly on their under side. *Ketmia palustris* flore purpureo. Tourn. Inst. 100. Marsh *Ketmia* with a purple flower.
 19. *HIBISCUS* (*Trionum*) foliis tripartitis incisfis, calycibus inflatis. Hort. Upsal. 206. *Hibiscus* with tripartite cut leaves, and a swollen empalement. *Ketmia vesicaria* vulgaris. Tourn. Inst. Common Bladder *Ketmia*, called Venice Mallow, or Flower of an hour.
 20. *HIBISCUS* (*Africana*) foliis tripartitis dentatis, lobis angustioribus caule hirsuto calycibus inflatis. *Hibiscus* with tripartite indented leaves having narrower lobes, a hairy stalk, and swollen empalements. *Ketmia vesicaria* Africana. Tourn. Inst. 101. African Bladder *Ketmia*.
 21. *HIBISCUS* (*Hispidus*) foliis inferioribus trilobis, summis quinque partitis obtusis crenatis calycibus inflatis, caule hispido. *Hibiscus* with under leaves having three lobes, the upper being cut into five obtuse segments, which are crenated, swollen empalements, and a prickly stalk.
 22. *HIBISCUS* (*Malvaviscus*) foliis cordatis-crenatis, angulis lateralibus extimis parvis, caule arboreo. Hort. Cliff. 349. *Hibiscus* with heart-shaped crenated leaves, whose outward lateral angles are small, and a tree-like stalk. *Malvaviscus* arborescens, flore miniato clauso. Hort. Elth. 210. tab. 170. Tree-like, viscous, seeded Mallow, with a closed scarlet flower.
- The first sort is commonly called *Althæa frutex* by the nursery gardeners, who propagate the shrubs for sale; of this there are four or five varieties, which differ in the colour of their flowers; the most common hath pale purple flowers with dark bottoms; another hath bright purple flowers with black bottoms; a third hath white flowers with purple bottoms; a fourth variegated flowers with dark bottoms; and a fifth pale yellow flowers with dark bottoms; but the last is very rare at present in the English gardens; there are also two with variegated leaves, which are by some much esteemed.
- This grows naturally in Syria, from whence it has been introduced to the gardens, and is one of the great ornaments of the autumn season: it rises with a shrubby stalk

stalk to the height of six or seven feet, sending out many ligneous branches, covered with a smooth gray bark, garnished with oval spear-shaped leaves, whose upper parts are frequently divided into three lobes, which are sawed; these are placed alternately on the branches, standing on short foot-stalks. The flowers come out from the wings of the stalks at every joint of the same year's shoot; they are large, and shaped like those of the Mallow, having five large roundish petals, which join at their base, spreading open at the top in shape of an open bell: these appear in August, and if the season is not too warm, there will be a succession of flowers part of September; the early flowers are succeeded by short capsules with five cells, filled with kidney-shaped seeds; but unless the season proves warm, they will not ripen in this country.

It is propagated by seeds, which should be sown in pots filled with light earth the latter end of March; and if they are plunged into a gentle heat, it will greatly forward the growth of the seeds. When the plants are come up, they must be inured to the open air, and in May the pots may be plunged into the ground, in a border exposed to the east, where they may have the morning sun: the reason of my advising the pots to be plunged into the ground, is to prevent the earth from drying so fast as it would do when the pots stand on the surface, so that the plants will not require so much water in summer; these plants will require no other culture, but to keep them clean from weeds, and in very dry weather to refresh them with water during the first summer, but in autumn it will be proper to remove the pots under a common frame to screen them from the frost; or where there is not such convenience, they may be plunged close to a hedge, pale, or wall, to a good aspect; and in severe frost, they should be covered with mats, straw, or other light covering; for although these plants, when they have obtained strength, will resist the cold of our winters, yet the young plants, whose shoots are tender, are very often injured by the first frost of autumn: so that if they are not screened the first year, they are often killed to the ground. Toward the latter end of March will be a good time to transplant these plants, at which time a spot of light ground must be prepared to receive them, which should be divided into beds four feet broad, with paths of two feet broad between; then the plants should be shaken out of the pots with the earth about them, and separated with care, for their roots are very tender, and apt to break with little force; these should be planted at about nine inches asunder in the beds; so that if four rows are planted in each bed, there will be six inches allowed between the outside rows and the paths. The ground should be gently closed about the roots to prevent the air penetrating to them; and if a little old tanners bark, or mulch, is laid over the surface of the beds, it will prevent the earth from drying, and be of great use to the plants; during the following summer they must be kept clean from weeds, and if the following winter prove severe, it will be prudent to cover the plants again in autumn, especially if they shoot late in the season, or the autumn proves cold and moist, for then the plants will be in great danger of having their tops killed: in these beds the plants may remain two years, by which time they will be fit to transplant where they are designed to remain; for if they are kept longer in the nursery, they will not remove so well. The best time for transplanting these plants is the end of March, or the beginning of April, for they seldom begin to shoot till the end of April, or the beginning of May; they should have a light soil, not too wet, for in strong land their stems grow mossy, and they never thrive after.

These plants may also be propagated by cuttings, which, if planted the latter end of March, in pots filled with light earth, and plunged into a gentle heat, will take root; but the plants so raised, are not so good as the seedlings. The several varieties may be

propagated by grafting upon each other, which is the common method of propagating the sorts with striped leaves.

The second sort grows naturally in India, from whence the French first carried the seeds to their settlements in the West-Indies; and the inhabitants of the British colonies there have been supplied with the seeds from them, so have given it the title of Martinico Rose: of this there are the double and single flowering, which from the seeds of the double the single is frequently produced, but the seeds of the single seldom vary to the double. The flowers of these plants alter in their colour, for at their first opening they are white, then they change to a blush Rose colour, and as they decay they turn to a purple. In the West-Indies, all these alterations happen the same day, as I suppose the flowers in those hot countries are not of longer duration: but in England, where the flowers last near a week in beauty, the changes are not so sudden.

This plant has a soft spongy stem, which, by age, becomes ligneous and pithy. It rises to the height of twelve or fourteen feet, sending out branches on every side toward the top, which are hairy, garnished with heart-shaped leaves, cut into five acute angles on their borders, and are slightly sawed on their edges, of a lucid green on their upper side, but pale below, standing alternately upon pretty long foot-stalks. The flowers are produced from the wings of the stalk, like those of the first sort; the single one is composed of five large petals, which spread open, and are first white, but afterward change in the manner before-mentioned; these are succeeded by short, thick, blunt capsules, which are very hairy, having five cells, which contain many small kidney-shaped seeds, having a fine plume of fibrous down adhering to them.

This sort is propagated by seeds, which must be sown upon a hot-bed in the spring, and when the plants are fit to remove, they should be each planted in a separate small pot filled with kitchen-garden earth, and plunged into a moderate hot-bed, where they must be shaded till they have taken new root; then they must be treated as other plants from warm countries, but not too tenderly; for these require a large share of air in warm weather, otherwise they will draw up very weak: these plants should not be quite exposed to the open air the first season, and the first winter will require the warmth of a moderate stove; but as they get more strength, they may be treated with less care, for they will bear the open air in summer, in a warm sheltered situation, and will live through the winter in a very good green-house, provided they have not too much wet; but the plants thus hardly treated, will not make so great progress, nor flower so well as with a little additional warmth; and if they are too tenderly managed, they will draw up weak, so will be less likely to flower. This sort usually flowers in England in November, so that it keeps to the usual time of flowering in its native country.

The third sort grows naturally in the West-Indies, where it is commonly known by the title of Musk; the French cultivate great quantities of these plants in their American Islands, the seeds of which are annually sent to France in great quantities, so that they certainly have some way of rendering it useful, as it seems to be a considerable branch of trade. This rises with an herbaceous stalk about three or four feet high, sending out two or three side branches, garnished with large leaves cut into six or seven angles, which are acute, and sawed on their edges; these stand on long foot-stalks, and are placed alternately. The stalks and leaves of this are very hairy. The flowers come out from the wings of the stalk upon pretty long foot-stalks, which stand erect; they are large, of a sulphur colour, with dark purple bottoms, and are succeeded by pyramidal five-cornered capsules, which open in five cells, filled with large kidney-shaped seeds of a very musky odour.

This

This sort seldom lives more than one year in England, but in its native country will last two years. It is propagated by seeds, which, if sown on a good hot-bed in the spring, and the plants afterward planted in pots filled with light earth, and plunged into a fresh hot-bed, treating them afterward in the same way as the *Amaranthus*, they will flower in July, and their seeds will ripen in autumn.

The fourth sort grows naturally in both the Indies; this rises with an herbaceous smooth stalk three or four feet high, garnished with leaves which are divided into seven segments almost to the bottom; the middle segment being four inches long and half an inch broad, the upper lateral segments about three inches long and the same breadth; these are indented at their extremities, but the lower segments are not much more than an inch long, and have foot-stalks four inches long. The flowers are produced from the wings of the stalks toward the top, standing on short foot-stalks; they are composed of five large sulphur-coloured petals, which, when open, spread five inches wide; they have a dark purple bottom, with a column of stamina and styles rising in the center, and are succeeded by large, pyramidal, five-cornered, erect seed-vessels, opening in five cells, which are filled with pretty large kidney-shaped seeds, which have little smell or taste.

It is propagated by seeds in the same manner as the former sort, and if so managed, will produce flowers and perfect seeds the same season; but the plants may be continued through the winter in a moderate warmth, though few persons are at the trouble of preserving the plants after they have ripened their seeds, because the young plants make a better appearance.

The fifth sort grows naturally in the West-Indies, where it rises with a woody stalk seven or eight feet high, sending out many side branches toward the top, which are covered with a whitish bark, and garnished with angular heart-shaped leaves, which are woolly; they are about four inches long, and three broad toward their base, ending in acute points, and have several longitudinal veins. The flowers are produced from the wings of the stalk upon long foot-stalks; they are composed of five roundish petals, which are joined at their base, but spread open above, and are of a yellow colour, turning to a red as they decay; these are succeeded by large, obtuse, five-cornered, hairy seed-vessels, which open in five cells, filled with large kidney-shaped seeds.

This is propagated by seeds, which must be sown upon a hot-bed in the spring, and the plants afterward treated in the same way as the two last mentioned, during the first summer, but in the autumn they must be plunged into the tan-bed in the stove, where they should constantly remain, and be treated in the same way as other tender plants from the same country, giving them but little water in winter; the second year the plants will flower, but they have not as yet perfected seeds in England.

The sixth sort grows naturally in both Indies; this rises with a woody pithy stem eight or ten feet high, dividing into several branches toward the top, which are covered with a woolly down, and garnished with round heart-shaped leaves, ending in acute points; they are of a lucid green on their upper side, and hoary on their under, full of large veins, and are placed alternately on the stalks. The flowers are produced at the end of the branches in loose spikes; they are of a whitish yellow colour, and are succeeded by short acuminate capsules, opening in five cells, filled with large kidney-shaped seeds.

This sort is propagated in the same way, and the plants require the same treatment as the fifth, and flower the second year, provided they are brought forward, otherwise they will not flower before the third or fourth season; but they will bear the open air in summer, in a warm situation, though they will not make great progress there.

The seventh sort grows naturally on the coast of

Malabar, from whence I received the plants; this rises with a woody stalk twelve or fourteen feet high, dividing into many small branches toward the top, which are garnished with oval sawed leaves, ending in acute points; they are of a lucid green above, but are pale on their under side, and are placed without order. The flowers come out from the side of the branches, at the wings of the leaves, on pretty long foot-stalks; they are composed of many oblong roundish petals of a red colour, which expand like the Rose, the flowers being as large when fully blown, as the common red Rose, and as double. This is a perennial plant, which is propagated by cuttings; and the plants must constantly be kept in the stove, giving them a large share of air in warm weather, and but little water in winter. There is a variety of this with white flowers, but I have not seen any of the plants in the English gardens; nor have I seen the single flowering kind, for the inhabitants of India propagate that with double flowers by cuttings, which put out roots freely; this they do for the sake of flowers, which the women of that country make use of to colour their hair and eye-brows black, which will not wash off: the English there use it for blacking of their shoes, and from thence have titled it Shoe-flower.

The eighth sort is an annual plant, which rises with an upright stalk seven or eight feet high; the lower leaves are oval, serrated, and entire, but the upper leaves are divided almost to the foot-stalk, into five spear-shaped segments, like the fingers of a hand, standing on very long foot-stalks, which have thorns at their base, and are sharply sawed on their edges. The flowers come out from the wings of the stalks; they are large, of a pale sulphur colour, with a dark purple bottom, and are succeeded by oval, acuminate, prickly capsules, which open in five cells, filled with large kidney-shaped seeds.

This sort is propagated by seeds, which must be sown upon a hot-bed, and the plants treated in the same way as the third sort; and when they are grown too tall to stand under the frames, they must be placed in the stove, where they will flower in August, and the seeds will ripen in autumn.

The ninth sort is near of kin to the eighth, but the stalks do not grow so tall; the lower leaves are heart-shaped and entire, the middle leaves are divided into three, and the upper into five segments, almost to the foot-stalks; they are sawed on their edges, and the stalk is prickly. The flowers come out from the wings of the stalks; they are of a very pale sulphur colour, with dark bottoms, but not so large as those of the last.

This is propagated by seeds in the same way as the eighth, and the plants require the same treatment. It flowers in July and August, and the seeds ripen in autumn.

The bark of both these plants is full of strong fibres, which I have been informed the inhabitants of the Malabar coast prepare and make into a strong cordage; and by what I have observed, it may be wrought into fine strong thread of any size, if properly manufactured.

The tenth sort grows naturally in the West-Indies, where the inhabitants use the green pods to add an acid taste to their viands: there are two varieties of this, one with a light green, and the other a deep red pod, which always maintain their difference; but as there is no other difference but that of the colour of their pods, they do not deserve separate titles. This rises with an herbaceous stem about three feet high, sending out several lateral branches, which are garnished with smooth leaves divided into five lobes. The flowers come out from the side of the branches; they are of a dirty white, with dark purple bottoms, and are succeeded by obtuse seed-vessels, divided into five cells, which are filled with kidney-shaped seeds.

This sort is propagated in the same way as the third, and will flower and perfect seeds the same year, so is seldom preserved longer in England.

H I B

The eleventh sort is a native of Ceylon; this rises with an herbaceous stalk, which is prickly, from two to three feet high, dividing upward into small branches, which are garnished with hand-shaped leaves, divided into five segments. The flowers come out from the wings of the leaves; they are small and white, with purple bottoms, and are succeeded by short obtuse capsules with five cells, filled with kidney-shaped seeds. The seeds of this sort were sent me by Dr. Breynius of Dantzick.

This plant is annual, so must be treated in the same way as the third.

The twelfth sort is also annual with us; this rises with an herbaceous stalk three feet high, closely set with prickly hairs, and divides into branches upward, garnished with hand-shaped leaves, divided into five lobes, which are spear-shaped, ending in acute points; they are hairy, and crenated on their edges, standing upon very long foot-stalks; the flowers come out from the wings of the stalk, and are very like those of the third; this plant requires the same culture as the third sort. The seeds of this were sent me by Dr. Jussieu, from Paris.

The thirteenth sort was discovered by the late Dr. Houstoun in the island of Cuba, from whence he sent me the seeds. This rises with a woody stalk twelve or fourteen feet high, sending out many lateral branches, garnished with hairy heart-shaped leaves, crenated on their edges; the flowers come out single from the wings of the leaves; they are of a very bright yellow colour, but not so large as either of the former sorts, and are succeeded by short capsules ending in acute points, divided into five cells, which are filled with kidney-shaped seeds. This plant is tender, so requires the same treatment as the fifth, and other tender kinds, with which management it flowers and produces good seeds here.

The fourteenth sort has a perennial root but an annual stalk. The seeds of this were sent me from the Bahama Islands, which succeeded in the Chelsea garden, where the plants produced plenty of flowers, but did not ripen their seeds. This rises with several stalks from the root, which grow four feet high, garnished with oblong, heart-shaped, smooth leaves, ending in acute points, of a light green on their upper side, but hoary on their under, and are slightly indented on their edges, standing upon long foot-stalks; the flowers are produced at the top of the stalks; they are very large, and of a light purple colour with dark bottoms, and are succeeded by short capsules divided into five cells, filled with kidney-shaped seeds.

This is propagated by seeds, which must be sown on a moderate hot-bed in the spring, and when the plants are fit to remove, they should be each planted in a separate small pot, and plunged into a hot-bed, treating them in the same way as the other tender sorts, but allowing them a greater share of air in warm weather; for these may be brought to stand in the open air in summer, but unless the season is very warm they will not flower there; for those which flowered in the Chelsea garden, were plunged into a tan-bed whose heat was declining, under a deep frame, where they produced plenty of flowers, but they came too late to ripen seeds. The stalks decay in the autumn, but if the pots are sheltered under a hot-bed frame and secured from frost, they will continue several years, and put out new stalks in the spring.

The fifteenth sort is very common in the West-Indies, where the inhabitants cultivate it for the pods or seed-vessels, which they gather green to put into their soups; these, having a soft viscous juice, add a thickness to their soups, and renders them very palatable. It rises with a soft herbaceous stalk, from three to five feet high, dividing upward into many branches, garnished with hand-shaped leaves, divided into five lobes; the flowers are produced from the wings of the stalk; they are of a pale sulphur colour with dark purple bottoms, but are smaller than either of the other sorts, and of very short duration, opening in the morning with the

H I B

rising sun, but are faded long before noon in warm weather. These are succeeded by capsules of very different forms, in the different varieties; in some the capsules are not thicker than a man's finger, and five or six inches long; in others they are very thick, and not more than two or three inches long; in some plants they grow erect, in others they are rather inclined; and these varieties are constant, for I have many years cultivated these plants, and have not found them vary.

This sort is propagated by seeds in the same way as the third, and the plants require the same treatment, for they are too tender to thrive in the open air in this country; I have often transplanted the plants into warm borders, after they have acquired proper strength, and have sometimes in very warm seasons had them thrive for a short time, but the first cold or bad weather their leaves have all dropped off; and then they have decayed gradually, so that they have but rarely flowered, and have never in the best seasons perfected their seeds; therefore those who are inclinable to cultivate these plants, must constantly shelter them in bad weather.

The sixteenth sort grows naturally near Venice, in moist land; this hath a perennial root, and an annual stalk, which rises from three to four feet high; the lower leaves are angular and heart-shaped, but the upper are spear-shaped, and slightly indented on their edges; the flowers are produced from the wings of the leaves, upon long foot-stalks; they are small, and of a purple colour with a dark bottom, and are succeeded by five-cornered compressed capsules, filled with kidney-shaped seeds.

This sort is propagated by seeds, which must be sown on a hot-bed, and the plants should be treated in the same way as the fourteenth sort, otherwise they will not flower; for although the roots will live in the full ground here, yet the summers are not warm enough to bring them to flower. I have some of the roots which have remained seven years, putting up many stalks, which rise upward of three feet, and have the flower-buds formed on their tops; but these appear so late in the season, that they seldom have opened.

The seventeenth sort grows naturally in North America; this hath a perennial root and an annual stalk; the roots of this sort will live in the full ground, but unless the summer is warm, the flowers seldom open. It rises with single stalks from the root, two feet high or more; the leaves are oval and sawed, the flowers are large and purple.

The eighteenth sort grows naturally in North America, in moist ground. This hath a perennial root, and an annual stalk like the former, which is herbaceous and never branches; the leaves are oval, with three lobes which are not deeply divided; they are of a bright green on their upper side, but woolly on their under; the flowers are produced from the wings of the stalk; they are large, and of a bright purple colour. This sort, like the former, seldom flowers in the open air here, unless the summer proves very warm, but the roots will live in the full ground, if they are planted in a sheltered situation. The only way to have these plants flower in this country, is to keep the roots in pots, and shelter them under a frame in winter, and in the spring plunge them into a gentle hot-bed, which will cause them to put out their stalks early; and when the stalks are so high as to reach the glasses, the pots may be removed into a glass-case; where, if they are duly supplied with water, and have plenty of air in hot weather, they will flower very well in July, and in warm seasons will ripen their seeds.

The nineteenth sort is an annual plant, which grows naturally in some parts of Italy, and has been long cultivated in the English gardens; by the title of Venice Malva. Gerard and Parkinson title it *Alcea Veneta*, and *Flos Hora*, or Flower of an hour, from the short duration of its flowers, which in hot weather continue but few hours open: however, there

is a succession of flowers which open daily for a considerable time, so that a few of these plants may be allowed a place in every curious garden.

It rises with a branching stalk a foot and a half high, having many short spines which are soft, and do not appear unless closely viewed: the leaves are divided into three lobes, which are deeply jagged almost to the midrib; these jags are opposite, and the segments are obtuse; the flowers come out at the joints of the stalks upon pretty long foot-stalks, having a double empalement, the outer being composed of ten long narrow leaves, which join at their base; the inner is of one thin leaf, swollen like a bladder, cut into five acute segments at the top, having many longitudinal purple ribs, and is hairy; both these are permanent, and inclose the capsule after the flower is past. The flower is composed of five obtuse petals, which spread open at the top, the lower part forming an open bell-shaped flower; these have dark purple bottoms, but are of a pale sulphur colour above, having the stamina and apices joined in a column in the center; after the flower is past, the germen turns to a blunt capsule opening in five cells, which are filled with small kidney-shaped seeds. It flowers in June, July, and August, and the seeds ripen about a month after. This sort is propagated by seeds, which should be sown where the plants are designed to remain, for they do not bear transplanting well; if the seeds are sown in autumn, the plants will come up early in the spring, so will flower in the summer, and those which are sown early in the spring will succeed them; so that by sowing them at three different seasons, they may be continued in succession till the frost stops them. These require no other culture but to keep them clean from weeds, and thin them where they are too close; and if the seeds are permitted to scatter, the plants will come up full as well as when sown, so that it will maintain its situation unless it is weeded out.

The twentieth sort grows naturally at the Cape of Good Hope; this is also an annual plant which resembles the former, but the stalks grow more erect, are of a purplish colour, and very hairy; the leaves are composed of three lobes, which are divided almost to the foot-stalk; these are narrow, the middle lobe stretching out more than twice the length of the two side lobes, and they are but slightly indented on their edges, whereas those of the former are cut almost to the midrib; the flowers are larger, and their colour deeper, than those of the other.

The seeds of the twenty-second sort were sent me from the Cape of Good Hope, a few years past. This is also an annual plant, having at first sight some resemblance of the other sorts before-mentioned; but it rises with strong hairy branching stalks, garnished with much broader leaves than either of the former, the lower being divided into three, and the upper into five obtuse lobes, which are crenated on their edges; the flowers are large, but of a paler colour than those of the other. This has maintained the difference ten years, so that there is no doubt of its being a distinct species.

All these are as hardy as the nineteenth sort, so may be treated in the same way.

The twenty-third sort grows naturally at Campeachy, from whence the late Dr. Houstoun sent me the seeds. This differs so essentially from the other species in its fructification, as to deserve another title; for all the other have dry capsules with five cells, including many kidney-shaped seeds, but this hath a soft viscid berry, with a hard shell inclosed, containing five roundish seeds: it rises with a shrubby stalk ten or twelve feet high, dividing into many branches, which are garnished with smooth, heart-shaped, angular leaves, which are crenated on their edges; the flowers come out from the wings of the stalks singly, standing on short foot-stalks; they are composed of five oblong petals, which are twisted together and never expand; they are of a fine scarlet, and are succeeded by roundish berries of a scarlet colour when ripe, in-

closing a hard shell which opens in five cells, each containing a single roundish seed.

This sort is generally propagated here by cuttings, because the seeds do not often ripen here; if the cuttings are planted in pots filled with light earth, and plunged into a gentle hot bed, keeping the air from them, they will soon take root, and should be gradually inured to bear the open air. These plants require a moderate stove to preserve them through the winter; and if they are kept in warmth in summer, they will flower, and sometimes ripen fruit, though they may be placed abroad in a sheltered situation for two or three months in summer, but the plants so treated seldom flower so well.

HIERACIUM. Lin. Gen. Plant. 818. Tourn. Inst. R. H. 469. tab. 267. [of *Ἱέραξ*, Gr. a hawk; so called, because hawks as well as eagles, have a strong and quick sight; and it is reported, that if by reason of the heat of the air, a film grows over the eyes of this bird, then the parent let falls a drop of the juice of it in its eye, which takes it off; and that, in like manner, it is good to clear the human sight.] Hawkweed.

The CHARACTERS are,

It hath a flower composed of many hermaphrodite florets, which are included in one common scaly empalement, whose scales are narrow, and very unequal in their length and position; the florets are equal and uniform; they have one petal which is shaped like a tongue, indented in five segments at the point, placed imbricatum over each other; these have each five short hairy stamina, terminated by cylindrical summits. At the bottom of the petal is situated the germen, supporting a slender style, crowned by two recurved stigmas; the germen afterward becomes a short four-cornered seed crowned with down, sitting in the empalement.

This genus of plants is ranged in the first section of Linnaeus's nineteenth class, which includes the plants with a compound flower, composed only of fruitful florets.

There are a great number of species of this genus, many of which grow naturally as weeds in England, and the others are so in different countries, therefore I shall only select those which are the most beautiful, and best worth cultivating from the number, which to enumerate, would swell this work greatly beyond its bounds.

1. **HIERACIUM** (*Aurantiacum*) foliis integris caule subnudo simplicissimo piloso corymbifero. Hort. Cliff. 388. *Hawkweed with entire leaves, and a single, hairy, naked stalk, terminated by a corymbus of flowers.* Hieracium hortense, floribus atro purpurascens. C. B. P. 128. *Garden Hawkweed with dark purple flowers.*

H I L

6. **HIERACIUM** (*Umbellatum*) foliis linearibus subdenticatis sparsis, floribus subumbellatis. Flor. Lapp. 287. *Hawkweed with linear indented leaves placed thinly, and flowers almost in an umbel.* Hieracium fruticosum, angustissimo incano folio. H. L. 316.

The first sort grows naturally in Syria; this sends out from the root many oblong oval leaves, which are entire and hairy; from between the leaves arise a single stalk, little more than a foot high, covered with hairs; the flowers are produced in a corymbus at the top; they are of a dark red colour, composed of many florets, which are succeeded by oblong black seeds, crowned with a white down, which, when ripe, by the elasticity of the down, is drawn out of the empalement, and by the first strong gale of wind, are waisted to a considerable distance. The flowers appear the beginning of June, and the seeds ripen in about five or six weeks after, but there is frequently a succession of flowers till the autumn.

It is propagated by seeds, which should be sown on an east aspected border in March; and when the plants come up, they must be kept clean from weeds, till they are strong enough to remove, which will be by the beginning of June; then they should be transplanted to a shady border of undunged ground, at six inches distance, observing to water them if the weather should prove dry, till they have taken new root; after which, if they are kept clean from weeds, they will require no other culture: in the autumn they should be transplanted where they are designed to remain; the following summer they will flower and produce ripe seeds, and the roots will continue some years, if they are not planted in a rich moist soil, which frequently occasions their rotting in winter.

The second sort grows naturally on the Pyrenean mountains. It is a perennial plant, whose lower leaves are oval, indented, and of a grayish colour; those on the stalks are smaller, but of the same shape and colour, and half embrace the stalks with their base; the stalks rise a foot high, branching out in several divisions, each being terminated by one yellow flower. This is propagated by seeds as the first sort.

The third sort grows on the Pyrenees; this hath a perennial root, which sends up several erect stalks, garnished with spear-shaped leaves which are indented; the flowers are produced from the wings of the stalks, upon short foot-stalks, each sustaining one large yellow flower, having a loose empalement; this flowers in June; it is propagated by parting of the roots in autumn, and will thrive in any situation.

The fourth sort rises with a branching stalk a foot and a half high, garnished with heart-shaped leaves which are indented at their base, where they embrace the stalks; each division of the branches terminate in a hairy foot-stalk, sustaining one large yellow flower, which appears in June, and the seeds ripen in the end of July. This is a perennial plant, which is propagated by seeds as the first sort, and requires the same treatment.

The fifth sort grows naturally in Savoy; the root of this is perennial, sending up several erect stalks near two feet high, garnished with short, spear-shaped, indented leaves, half embracing the stalk with their base; the flowers are pretty large, of a deep yellow colour, terminating the stalks; it flowers in July.

The sixth sort grows naturally in Holland; it is a perennial plant, rising with three or four slender stalks, garnished with hoary linear leaves, and terminated by yellow flowers. This rarely produces seeds in England, so is propagated by parting of the roots in autumn: but the fifth may be propagated either in the same manner, or from seeds as the first sort, as it produces plenty of seeds here.

HILLS have many uses, of which I shall only mention three or four.

1st, They serve as screens, to keep off the cold and nipping blasts of the northern and eastern winds.

2dly, The long ridges and chains of lofty mountains,

H I P

being generally found to run from east to west, serve to stop the evagation of those vapours toward the poles, without which they would all run from the hot countries, and leave them destitute of rain.

3dly, They condense those vapours, like alembic heads into clouds; and so by a kind of external distillation, give origin to springs and rivers; and by amassing, cooling, and constipating them, turn them into rain, and by that means render the fervid regions of the torrid zone habitable.

4thly, They serve for the production of a great number of vegetables and minerals, which are not found in other places.

It hath been found by experience and calculation, that Hills, though they measure twice as much as the plain ground they stand upon, yet the produce of the one can be no more than the other; and therefore, in purchasing land, the Hills ought not to be bought for more than their superficial measure, i. e. to pay no more for two acres upon the side of a Hill, than for one upon the plain, if the soil be equally rich.

It is true, that those lands that are hilly and mountainous, are very different as to their valuable contents, from what are found in flat and plain ground, whether they be planted, sown, or built upon, as for example:

Suppose a Hill contains four equal sides, which meet in a point at top; yet the contents of these four sides can produce no more grain, or bear no more trees, than the plain ground on which the Hill stands, or than the base of it; and yet by the measure of the sides, there may be double the number of acres, rods, and poles, which they measure on the base or ground-plot.

For as long as all plants preserve their upright method of growing, hilly ground can bear no more plants in number than the plain at the base.

Again, as to buildings on a Hill, the two sides of a Hill will bear no more than the same number of houses that can stand in the line at the base.

And as to rails, or park paling over a Hill, though the measure be near double over the Hill to the line at the bottom, yet both may be inclosed by the same number of pales of the same breadth.

HIPPOCASTANUM. See ESCULUS.

HIPPOCRATEA. Lin. Gen. Plant. 54. Coa. Plum. Nov. Gen. 8. tab. 35.

The CHARACTERS are,

It hath a large spreading empalement of one leaf, cut at the top into five segments; the flower hath five oval petals, which are indented at the points. It hath three awl-shaped stamina, terminated by broad summits, and an oval germen situated below the petal, with a style the length of the stamina, crowned by an obtuse stigma. The germen afterward becomes a heart-shaped capsule winged at the top, inclosing five seeds.

This genus of plants is ranged in the first section of Linnæus's third class, intitled Triandria Monogynia, the flowers having three stamina and one style.

We have but one SPECIES of this genus, viz.

HIPPOCRATEA (*Volubilis.*) Lin. Sp. 50. Plum. Gen. 8.

Hippocratea with a triple roundish fruit and a twining stalk. Coa scandens, fructu trigemino subrotundo. Plum. Nov. Gen. 8. Climbing Coa with a triple roundish fruit.

The seeds of this plant were sent me from Campeachy by Mr. Robert Millar, and several of the plants were raised in England, which continued two years in several gardens, but not one of them lived to flower; they grew to the height of eight or ten feet, twining round stakes, but their stalks were very slender, and decayed at the bottom, probably from their having too much wet.

It is a very tender plant, so must be constantly kept in the bark-bed in the stove, and should have but little wet in winter.

HIPPOCREPIS. Lin. Gen. Plant. 791. Ferum equinum. Tourn. Inst. 400. tab. 225. Horse-shoe Vetch; in French, *Fer de Cheval.*

The

H I P

The CHARACTERS are,

The empalement of the flower is permanent, of one leaf, divided into five parts, the two upper being joined. The flower is of the butterfly kind; the standard hath a narrow base the length of the empalement, but is heart-shaped above; the wings are oval, oblong, and blunt; the keel is moon-shaped and compressed. It hath ten stamina, nine joined and one separate, which stand erect, terminated by single summits. It hath an oblong narrow germen, sitting on an awl-shaped style, crowned by a single stigma. The germen afterward becomes a long, plain, compressed pod, which is cut into many parts from the under seam to the upper, each part forming a roundish sinus, with obtuse three-cornered joints connected to the upper seam, each joint being shaped like a horse-shoe, inclosing a single seed.

This genus of plants is ranged in the third section of Linnæus's seventeenth class, intitled Diadelphia Decandria, which includes the plants with a leguminous flower, having ten stamina joined in two bodies.

The SPECIES are,

1. HIPPOCREPIS (*Unifiliquosa*) leguminibus sessilibus solitariis. Hort. Cliff. 364. *Horse-shoe Vetch with single pods sitting close to the stalk.* Ferrum equinum, siliquâ singulari. C. B. P. 349. *Horse-shoe Vetch with a single pod.*
2. HIPPOCREPIS (*Comosa*) leguminibus pedunculatis confertis, margine exteriore repandis. Prod. Leyd. 384. *Horse-shoe Vetch, with pods growing in clusters upon foot-stalks, whose outer border is turned inward.* Ferrum equinum Germanicum, siliquis in summitate. C. B. P. 346. *German Horse-shoe Vetch having pods on the tops of the stalks.*
3. HIPPOCREPIS (*Multifiliquosa*) leguminibus pedunculatis confertis, margine altero lobatis. Hort. Cliff. 364. *Horse-shoe Vetch with pods growing in clusters upon foot-stalks, one border of which has lobes.* Ferrum equinum siliquâ multiplici. C. B. P. 346. *Horse-shoe Vetch with many pods.*

The first sort grows naturally in Italy and Spain. This is an annual plant, which sends from the root several trailing stalks a foot long, that divide upward into smaller branches, garnished with winged leaves, composed of four or five pair of narrow small lobes, terminated by an odd one, which are obtuse, and indented at their ends; from the wings of the stalk come out single flowers of the butterfly kind, which are yellow, and succeeded by single pods sitting close to the stalks, which are about two inches long, and a third of an inch broad, bending inward like a sickle, and divided into many joints shaped like a horse-shoe. This flowers in June and July, and the seeds ripen in the autumn, soon after which the plants decay.

The second sort is found growing naturally in some parts of England, upon chalky hills, particularly at Hogmagog hills near Cambridge; this is a smaller plant than the former, and hath a perennial root, sending out slender trailing stalks about six inches long, which are garnished with narrow winged leaves; the flowers grow in clusters on the top of long foot-stalks; these are succeeded by pods which are shorter, and twisted inward in roundish curves, but have joints shaped like those of the former sort.

The third sort grows naturally in the south of France, Germany, and Italy. This is an annual plant, with trailing stalks greatly resembling the first, but the flowers are produced in clusters on the top of pretty long foot-stalks; they are shaped like those of the other sorts, and the pods are jointed in like manner, but the joints are fixed to the opposite border. These plants flower in June and July, and the seeds ripen in August and September.

These plants are propagated by seeds, which should be sown in the autumn, where the plants are designed to remain; and when the plants come up, they must be kept clean from weeds, and thinned where they are too close, which is all the culture they require.

The two annual sorts will decay in the autumn after they have perfected their seeds, but the roots of the

H I P

other will continue two or three years, provided they are not in too good ground.

HIPPOLAPATHUM. See RUMEX.

HIPPOMANE. Lin. Gen. Plant. 1099. Mançanilla. Plum. Nov. Gen. 50. tab. 30. The Manchineel.

The CHARACTERS are,

It hath male and female flowers in the same spike; the male flowers come out in small clusters, from a small cup-shaped empalement; these have no petals; from the center of each empalement arises a single style, terminated by two bifid summits. The female flowers have no petal, but an oval germen wrapped up in a three-leaved empalement; they have no style, but are crowned by a tripartite bifid stigma. The germen afterward becomes a roundish fruit with a fleshy cover, inclosing a rough hard shell with several cells, each inclosing one oblong seed.

This genus of plants is ranged in the ninth section of Linnæus's twenty-first class, which includes the plants with male and female flowers, which have but one stamina.

The SPECIES are,

1. HIPPOMANE (*Mançinella*) foliis ovatis serratis. Hort. Cliff. 484. *Hippomane with oval sawed leaves.* Mançanilla pyric facie. Plum. Nov. Gen. 50. *Manchineel with the appearance of the Pear-tree.*
2. HIPPOMANE (*Biglandulosa*) foliis ovato-oblongis, basi glandulosis. Lin. Sp. Plant. 1431. *Hippomane with oval oblong leaves, which have glands at their base.* Mançanilla lauri foliis oblongis. Plum. Nov. Gen. 50. *Manchineel with oblong Bay leaves.*
3. HIPPOMANE (*Spinosa*) foliis subovatis dentato spinosis. Lin. Gen. Plant. 1191. *Hippomane with oval leaves which have prickly indentures.* Mançanilla aqui-folii foliis. Plum. Nov. Gen. 50. *Manchineel with Holly leaves.*

The first sort grows naturally in all the islands of the West-Indies. This is a very large tree in its native soil, almost equalling the Oak in size; the wood is much esteemed for making of cabinets, book-cases, &c. being very durable, and taking a fine polish; it is also said, that the worms will not eat it: but as the trees abound with a milky caustic juice, so before they are felled, they make fires round their trunks to burn out their juice, otherwise they who fell them, would be in danger of losing their sight, by the juice flying in their eyes; and wherever this falls on the skin, it will raise blisters; and if it comes upon linen, it will immediately turn it black, and on being washed will come into holes: it is also dangerous working of the wood after it is sawn out, for if any of the saw-dust happens to get into the workmens eyes, it causes inflammations, and the loss of sight for some time; to prevent which, they generally cover their faces with fine lawn, during the time they are working the wood.

This tree hath a smooth brownish bark; the trunk divides upward into many branches, which are garnished with oblong leaves about three inches long, and one inch and a half broad, ending in acute points; they are slightly sawed on their edges, and are of a lucid green, standing on short foot-stalks. The flowers come out in short spikes at the end of the branches, being of both sexes in the same spike, but having no petals they make but little appearance; these are succeeded by fruit, about the size and of the same shape as the Golden Pippin, turning of a yellow colour when ripe, which has often tempted strangers to eat of them to their cost, for they inflame the mouth and throat to a great degree, causing violent pains in the throat and stomach, which is dangerous, unless remedies are timely applied.

The inhabitants of America believe it is dangerous to sit or lie under these trees, and affirm, that the rain, or dew, which falls from the leaves, will raise blisters; but it is very certain, that unless the leaves are broken, and the juice of them mix with the rain, it will do no injury.

The second sort grows naturally at Carthagena in New Spain, and the third at Campeachy, from which places

places the late Dr. Houftoun sent me their seeds. The second sort grows to as large a size as the first. The leaves of this are much longer than those of the first, and have two small glandules growing at their base; they are sawed on their edges, and are of a lucid green.

The third sort is of humbler growth, seldom rising more than twenty feet high; the leaves of this greatly resemble those of the common Holly, and are set with sharp prickles at the end of each indenture; they are of a lucid green, and continue all the year. These plants are preserved in some of the curious gardens in Europe, where they can never be expected to rise to any great height, for they are too tender to live in these northern countries, but in stoves; they rise easily from seeds, provided they are good. The seeds must be sown upon a good hot-bed, and when the plants come up, they should be each planted in a small separate pot filled with light sandy earth, and plunged into a good bed of tanners bark, treating them in the same way as other tender plants; but they must not have much wet, for these plants abound with an acrid milky juice, and it is certain that most plants which do, are soon killed by much moisture: these plants must be removed into the stove, and plunged into the tan-bed in autumn, where they should constantly remain, giving them very little water in winter; and in summer when the weather is warm, they should have a good share of air admitted to them, and once or twice a week refreshed with water; by this management I have raised many of these plants to the height of five or six feet, which have, by their shining green leaves, made a pretty variety during the winter season in the stove.

HIPPOPHAE. Lin. Gen. Plant. 980. Rhamnoides. Tourn. Cor. 52. tab. 481. Bastard Rhamnus, or Sea Buckthorn.

The CHARACTERS are,

It is male and female in different plants; the male flowers have an empalement of one leaf, cut into two segments, which close at their points; they have no petals, but have four short stamina, terminated by oblong angular summits, which are equal to the empalement. The female flowers have no petals, but have a one-leaved empalement, which is oval, oblong, tubulous, and bifid at the brim; these have no stamina, but in the center is situated a small roundish germen, with a short style, crowned by an oblong thick stigma, twice the length of the empalement. The germen afterward turns to a globular berry with one cell, inclosing one roundish seed.

This genus of plants is ranged in the fourth section of Linnæus's twenty-first class, intitled Diœcia Tetrandria, in which are included those plants which are male and female in distinct plants, and the male flowers have four stamina.

The SPECIES are,

1. **HIPPOPHAE** (*Rhamnoides*) *foliis lanceolatis.* Lin. Sp. Plant. 1023. *Hippophae with spear-shaped leaves.* Rhamnoides *salicis folio.* Tourn. Cor. 53. *Sea Buckthorn with a Willow leaf.*
2. **HIPPOPHAE** (*Canadensis*) *foliis ovatis.* Lin. Sp. Plant. 1024. *Hippophae with oval leaves, called Canada Sea Buckthorn.*

The first sort grows naturally on the sea banks in Lincolnshire, and also on the sand-banks between Sandwich and Deal, in Kent; there are two varieties of this, one with yellow, and the other with red fruit; but it is the first only which I have observed growing naturally in England; the other I saw growing on the sand-banks in Holland.

These rise with shrubby stalks eight or ten feet high, sending out many irregular branches, which have a brown bark silvered over, garnished with very narrow spear-shaped leaves, about two inches long, and a quarter of an inch broad in the middle, lessening gradually to both ends, of a dark green on their upper side, but hoary on their under, having a prominent midrib; the two borders of the leaves are reflexed like the Rosemary; these are placed alternate on every side the branches, sitting very close. The flowers

come out from the side of the younger branches, to which they sit very close; the male flowers growing in small clusters, but the female come out singly; these make but little appearance. They appear in July, and the berries on the female plants are ripe in autumn.

This sort is easily propagated by suckers from the root, for the roots spread wide, and send up a great number of shoots, so as to form a thicket: if these are taken off in autumn, and transplanted into a nursery, they will be fit to transplant after one year's growth, to the places where they are to remain: as there is little beauty in this plant, so one or two of them may be allowed a place in a plantation of shrubs for the sake of variety.

The second sort grows naturally in North America; this hath much the appearance of the former sort, but the leaves differ in their shape, these being much shorter and broader, and are not so white on their under side. This hath not as yet flowered in this country, but the plants seem equally hardy with the former, and may be easily propagated by suckers or layers.

HIPPOSELINUM. See SMYRNIUM.

HIRUNDINARIA. See ASCLEPIAS.

HOEING is necessary and beneficial to plants, for two things: 1st, For destroying of weeds; 2dly, Because it disposes the ground better to imbibe the night dews, keeps it in a constant freshness, and adds a vigour to the plants and trees, whose fruit by that means, becomes better conditioned than otherwise it would be.

This operation is performed by the hand, with an instrument called a Hoe, which is well known to every gardener. There are several sizes of these; the smallest, which is called an Onion Hoe, is not more than three inches broad, and is used for Hoeing of Onions; not only to cut up the young weeds, but also to thin the Onions, by cutting up all those which are too close. The next size is near four inches and a half broad, and is called a Carrot Hoe; this is used for Hoeing of Carrots, or any other crop which requires the same room as those. The largest size is about seven inches broad, and is frequently called a Turnep Hoe, being used for Hoeing of Turneps; but this is generally used by the kitchen-gardeners, for Hoeing between all their crops which are planted out, or stand so far asunder as to admit an instrument of this breadth to pass between the plants. Beside, these sort of Hoes, which are contrived to draw toward the person who uses them, there is another sort of a different form, which is called a Dutch Hoe; this is made for the person who uses it to push from him, so that he does not tread over the ground which is hoed. This is a very proper instrument for scuffling over the ground to destroy weeds, in such places where the plants will admit of its being used, and a person will go over a much greater space of ground in the same time with one of these instruments; than with the common Hoe; but this instrument is not so proper for Hoeing out crops, so as to leave the plants at a proper distance, nor will it penetrate the ground so far; therefore the other sort of hoe is to be preferred to this, because it stirs the ground and loosens the surface, whereby the dews penetrate the ground, and thereby promote the growth of the plants. Of late years there has also been another instrument introduced in the field culture, called the Horse Hoe; which is a sort of plough with the shear set more inclining to a horizontal position than the common plough; but as most of the farmers are at a loss how to use this instrument, so it has been but little practised in this country as yet; nor is it likely to be brought into use, unless the garden farmers near London, who are undoubtedly the best husbandmen in Europe, introduce it; for the common farmers can never be supposed to alter their old established methods, till by necessity they are drove to it: a strong instance we have of this kind, in the culture of Turneps, which for many years were sown in most of the counties in England; but till within about sixty years past, they were never

H O L

hoed, except within twenty or thirty miles of London, where the gardeners who had been bred in the kitchen-gardens near London, every season went out in particular gangs to the different parts of the neighbouring country, and each party engaged to hoe the Turneps in such a particular district, at a certain price per acre; and from the success of the farmers who first employed them, their neighbours were at length tempted to follow their example, so that it became necessary for some of their labourers to understand this work; and from that time it has prevailed so much, as that many of the distant counties have now engaged in this practice: and if the Horse-hoeing husbandry was but well established among the farmers near London, there would be little doubt of its spreading into the distant counties; but there are great prejudices against it at present, most of them arising from the ignorance of the farmers in general, and others from the over-fondness of the author to his own schemes, which has in many particulars carried him into many known absurdities; and these being well known to every practical farmer and gardener, are sufficient arguments with them against making trial of the useful part of his scheme.

The utility of this method of husbandry, is first, in proportioning the number of plants to the pasture, which the ground is supposed capable of nourishing properly. The second is, by frequent stirring of the surface of the land, all weeds which rob the crop of its nourishment is destroyed, and the clods of earth are hereby divided and pulverized, so that the roots of the plants can more easily penetrate them, and search their proper food; besides, the dews and moisture are easily imbibed in the loose ground, whereby the plants receive a greater share of nourishment.

There are few persons who properly consider of what consequence the stirring and breaking of the surface of the ground is to all crops growing therein. I have frequently made trial of this, when the crop has been so bad as to be thought not worth standing, which has been occasioned by the great quantity of rain which has fallen, whereby the surface of the ground has been so closely bound, as that the plants could find no nourishment, but have changed their usual verdure to a purple colour, and have made no progress; but upon Hoeing the ground and breaking the clods, the plants have put out new roots, and have flourished exceedingly. From many repeated trials of this kind I can affirm, that if the Wheat in general was sowed in rows, so as that the plough may be brought between them in the spring, to loosen the ground, which by the winter's rains may have been too closely bound, the crop would more than double what is the common produce.

But the author of this scheme was too sanguine in his proposals, first, by asserting, that in this method of husbandry, the land would constantly produce the same sort of crops without diminution; and secondly, it might be done without dressing or manuring the ground; and his fondness for his own scheme carried him so far in the prosecution of it, as at last to have much worse crops than any of his neighbours; however, this should not discourage others from the practice of it, though upon different principles: for although the land thus cultivated, will not nourish the same plant without manuring several years, yet by this method of husbandry I can affirm, that all crops will be so much improved, as to doubly answer the difference of expence, and less than a sixth part of the seed will be enough for the same space of ground. The common swing plough will answer all intents of Horse-hoeing.

HOLCUS. Lin. Gen. Plant. 1015. Milium. Tourn. Inst. R. H. 514. tab. 298. Sorgum. Mich. Indian Millet, or Corn.

The CHARACTERS are,

It hath male and hermaphrodite flowers sometimes on the same plant, at others on different plants. The male flowers are small, and have a bivalve chaff; these valves are oval, spear-shaped, and twisted, ending with

H O R

an acute beard; they have a small hairy corolla with three hairy stamina, terminated by oblong summits. The hermaphrodite flowers are single, in a stiff bivalve chaff; the inner of these is slender, hairy, and less than the empalement; the outer valve terminates in a rigid beard, and is larger than the empalement; they have three hairy stamina, terminated by oblong summits, with a roundish germen, supporting two hairy styles, crowned with plumose summits. The germen afterward becomes an oval single seed wrapped up in the chaff.

This genus of plants is ranged in the first section of Linnæus's twenty-third class, intitled Polygamia Monœcia which includes those plants which have male and hermaphrodite flowers in different parts of the same plant, whose flowers have several stamina.

The SPECIES are,

1. **HOLCUS** (*Sorgum*) glumis villosis, seminibus aristatis. Hort. Upsal. 301. *Holcus with hairy chaff and bearded seeds.* Milium arundinaceum, subrotundo semine, Sorgo nominatum. C. B. P. 26. *Reed-like Millet, with a roundish seed, called Sorgum.*
2. **HOLCUS** (*Saccharatus*) glumis glabris, seminibus muticis. Lin. Sp. Plant. 1047. *Holcus with smooth husks, and seeds without awns.* Milium Indicum, arundinaceo caule, granis flavescens. H. L. 425. *Indian Millet with a reedy stalk, and yellowish grains.*

There are several other of the grassy tribe which belong to this genus, but as they are not cultivated for use, so I shall not enumerate them here.

The two sorts here mentioned, grow naturally in India, where their grain is often used to feed poultry, and the seeds of these are frequently sent to Europe for the same purpose; but the summers are seldom warm enough to ripen the seeds in the open air in England, but in Italy they are both cultivated. The stalks of these plants rise five or six feet high, which are strong reedy, and like those of the Maiz, or Turkey Wheat, but smaller. The leaves are long and broad, having a deep furrow through the center, where the midrib is depressed on the upper surface, and is very prominent below. The leaves are two feet and a half long, and two inches broad in the middle, embracing the stalks with their base. The flowers come out in large panicles at the top of the stalks, resembling, at first appearance, the male spikes of the Turkey Wheat; these are succeeded by large roundish seeds, which are wrapped round with the chaff. These plants are propagated in a few gardens for the sake of variety, but as they are late in ripening their grain here, so they are not worth cultivating for use. The seeds should be sown on a warm border, or upon a gentle hot-bed in March; and when the plants come up, they should be thinned and planted at the distance of a foot asunder in the rows, and the rows should be three feet distance; the culture after this, is to keep the ground clean from weeds, and draw the earth up with a hoe to the stems of the plants; if the season proves warm, their panicles will appear in July, and the grain will ripen in September, but in bad seasons their grain will not ripen here.

HORDEUM. Lin. Gen. Plant. 94. Tourn. Inst. R. H. 513. tab. 293. Barley; in French, Orge.

The CHARACTERS are,

It hath a partial involucre of six narrow-pointed leaves, which contain three flowers. The petal of the flower opens with two valves; the under valve is angular, swelling, oval, and pointed, being longer than the empalement, ending in a long beard; the inner is small and spear-shaped. The flower hath three hairy stamina shorter than the petal, terminated by oblong summits. It hath an oval turned germen, supporting two hairy reflexed styles, crowned by the like stigmas. The germen afterward becomes an oblong bellied seed,

seed, pointed at both ends, having a longitudinal furrow, surrounded by the petal of the flower, which does not fall off. This genus of plants is ranged in the second section of Linnæus's third class, which includes the plants whose flowers have three stamina and two styles.

The SPECIES are,

1. HORDEUM (*Vulgare*) flosculis omnibus hermaphroditis aristatis ordinibus duobus erectioribus. Lin. Sp. Plant. 84. Barley with all the flowers hermaphrodite, and two orders of beards, which are erect. Hordeum polypticum vernal. C. B. P. 22. Spring Barley with many rows of grain.
2. HORDEUM (*Zeocriton*) flosculis lateralibus masculis muticis, feminibus angularibus imbricatis. Hort. Upsal. 23. Barley with male flowers on the side, without awns, and angular seeds placed over each other. Hordeum distichon. C. B. P. 22. Common long-eared Barley.
3. HORDEUM (*Distichon*) flosculis lateralibus masculis muticis, feminibus angularibus imbricatis. Hort. Upsal. 23. Barley with male flowers on the side, without awns, and angular imbricated seeds. Hordeum distichum, spica brevior & latior, granis confertis. Raii Syn. 246. Barley with shorter and broader spikes, commonly called Sprat, or Battledore Barley.
4. HORDEUM (*Hexastichon*) flosculis omnibus hermaphroditis aristatis, feminibus sexfaris æqualiter positis. Hort. Upsal. 23. Barley with all the flowers hermaphrodite, bearded, and six rows of seeds equally ranged. Hordeum hexalticum pulchrum. J. B. 2. 429. Winter, or Square Barley, Bear Barley, or Big.

The first sort is the common Spring Barley, which is principally cultivated in England; of this the farmers make two sorts, viz. the common and rath-ripe Barley, which are the same: for the rath-ripe has only been an alteration, occasioned by being long cultivated upon warm gravelly lands. The seeds of this, when sown in cold or strong land, will the first year ripen near a fortnight earlier than the seeds taken from strong land; therefore the farmers in the vales, generally purchase their seed Barley from the warm land; for if sowed in the vales two or three years, it will become full as late in ripening as the common Barley of their own product; and the farmers on the warm land are also obliged to procure their seed Barley from the strong land, otherwise their grain would degenerate in bulk and fulness, which by thus changing is prevented. This sort of Barley is easily distinguished by the two orders of beards, or awns, which stand erect; the chaff is also thinner than that of the two last species, so is esteemed better for malting. The second sort is the long-eared Barley, which is cultivated in many parts of England, and is an exceeding good sort; but some farmers object to this sort, because they say the ears being long and heavy, it is more apt to lodge; this hath the grains regularly ranged in a double row, lying over each other like tiles on a house, or the scales of fishes. The husk, or chaff of this Barley is also very thin, so is much esteemed for malting.

The third sort is usually called Sprat Barley; this hath shorter and broader ears than either of the other sorts; the awns, or beards, are longer, and the grains are placed closer together, and the awns being long, the birds cannot so easily get out the grains; this seldom grows so tall as the other species, the straw is shorter and coarser, so not very good fodder for cattle. The fourth sort is rarely cultivated in the southern parts of England, but in the northern counties, and in Scotland, is generally sown, being much hardier than the other species, so will bear the cold; this hath its grains disposed in six rows: the grain is large and plump, but it is not so good for malting, which is the reason for its not being cultivated in the southern parts of England, where the other sorts, which are much better for that purpose, do thrive well.

All these sorts of Barley are sown in the spring of the year, in a dry time; in some very dry light land, the Barley is sown early in March; but, in strong clayey soils, it is not sown till April, and sometimes not until the beginning of May; but when it is sown late, if the season doth not prove very favour-

able, it is very late in autumn before it is fit to mow, unless it be the rath-ripe sort, which is often ripe in nine weeks from the time of sowing.

Some people sow Barley upon land where Wheat grew the former year; but when this is practised, the ground should be ploughed the beginning of October in a dry time, laying it in small ridges, that the frost may mellow it the better, and this will improve the land greatly; and if this can be ploughed again in January, or the beginning of February, it will break and prepare the ground better; then in March the ground is ploughed again, and laid even where it is not very wet; but in strong wet lands the ground should be laid round, and the furrows made deep to receive the wet. When this is finished, the common method is to sow the Barley-seed with a broad cast at two sowings; the first being harrowed in once, the second is harrowed until the seed is buried; the common allowance of seed is four bushels to an acre. This is the quantity of grain usually sown by the farmers; but if they could be prevailed on to alter this practice, they would soon find their account in it; for if less than half that quantity is sown, there will be a much greater produce, and the corn will be less liable to lodge, as I have many years experienced; for when corn or any other vegetable stands very close, the stalks are drawn up weak, so are incapable to resist the force of winds, or bear up under heavy rains; but when they are at a proper distance, their stalks will be more than twice the size of the other, so are seldom laid. I have frequently observed in fields where there has been a foot-path through the middle, that the corn which has stood thin on each side the path hath stood upright, when all the rest on both sides has been laid flat on the ground: and whoever will observe these roots of corn near the paths, will find them tiller out (i. e. have a greater number of stalks) to more than four times the quantity of the other parts of the field. I have seen experiments made by sowing Barley in rows across divers parts of the same field, and the grains sowed thin in the rows, so that the roots were three or four inches asunder in the rows, and the rows at a foot distance; the intermediate spaces of the same field were at the same time sown broad cast in the usual way; the success was this, the roots which stood thin in the rows tillered out from ten or twelve, to upward of thirty stalks on each root, the stalks were stronger, the ears longer, and the grains larger than any of those sown in the common way; and when those parts of the field where the corn was sown in the usual way has been lodged, these parts sown thin have supported their upright position against wind and rain, though the rows have been made not only lengthways, but cross the lands, in several positions, so that there could be no alteration in regard to the goodness of the land, or the situation of the corn; therefore where such experiments have been frequently made, and always attended with equal success, there can be no room to doubt which of the two methods is more eligible; since if the crops were only supposed to be equal in both, the saving more than half the corn sown is a very great advantage, and deserves a national consideration, as such a saving, in scarce times, might be a very great benefit to the public. I know the farmers in general are very apt to complain if their corn does not come up so thick as to cover the ground green in a short time, like Grass fields; but I have often observed, that from the badness of the season it has come up thin, or by accident has been in part killed, their corn has been stronger, the ears longer, and the grain plumper, so that the produce has been much greater than in those years when it has come up thick; for the natural growth of corn is to send out many stalks from a root, and not rise so much in height; therefore it is entirely owing to the roots standing too near each other, when the stalks are drawn up tall and weak. I have had eighty-six stalks upon one root of Barley, which were strong, produced longer ears, and the grain was better filled than any which I ever saw grow in the common method of husbandry, and the land upon which this grew

grew was not very rich: but I have frequently observed on the sides of hot-beds in the kitchen-gardens, where Barley-straw has been used for covering the beds, that some of the grains left in the ears has dropped out and grown, the roots have produced from thirty to sixty stalks each, and those been three or four times larger than the stalks ever arrive at in the common way: but to this I know it will be objected, that although upon rich land in a garden, these roots of corn may probably have so many stalks, yet in poor land they will not have such produce; therefore unless there is a greater quantity of seeds sown, their crop will not be worth standing, which is one of the greatest fallacies that can be imagined; for to suppose that poor land can nourish more than twice the number of roots in the same space as rich land, is such an absurdity, as one could hardly suppose any person of common understanding guilty of; and yet so it is, for the general practice is to allow a greater quantity of seed to poor land, than for richer ground; not considering that where the roots stand so close, they will deprive each other of the nourishment, so starve themselves, which is always the case where the roots stand close; which any person may at first sight observe, in any part of the fields where the corn happens to scatter when they are sowing it; or in places where, by harrowing, the seed is drawn in heaps, those patches will starve, and never grow to a third part of the size as the other parts of the same field; and yet common as this is, it is little noticed by farmers, otherwise they surely would not continue their old custom of sowing. I have made many experiments for several years in the poorest land, and have always found that all crops which are sown or planted at a greater distance than usual, have succeeded best; and I am convinced, if the farmers could be prevailed on to quit their prejudices, and make trial of this method of sowing their corn thin, they would soon see the advantage of this husbandry.

The noblemen and gentlemen in France are very busy in setting examples of this husbandry in most of their provinces, being convinced by many trials of its great utility; and it were to be wished, the same was done in England,

When the Barley is sown, the ground should be rolled after the first shower of rain, to break the clods and lay the earth smooth, which will render it better to mow, and also cause the earth to lie closer to the roots of the corn, which will be of great service to it in dry weather.

Where Barley is sown upon new broken up land, the usual method is, to plough up the land in March, and let it lie fallow until June, at which time it is ploughed again, and sown with Turneps, which are eaten by sheep in winter, by whose dung the land is greatly improved; and then in March following the ground is ploughed up again, and sown with Barley as before.

There are many people who sow Clover with their Barley, and some have sown the Lucern with Barley; but neither of these methods is to be commended, for where there is a good crop of Barley, the Clover or Lucern must be so weak as not to pay for standing; so that the better way is to sow the Barley alone without any other crop among it, and then the land will be at liberty for any other crop, when the Barley is taken off the ground; but this practice of sowing Clover, Rye-grass, and other Grass-seeds, with corn, has been so long and universally established among farmers, that there is little hope of prevailing with those people to alter a custom which has been handed down to them from their predecessors, although there should be many examples produced, to shew the absurdity of this practice.

When the Barley has been up three weeks or a month, it will be a very good method to roll it over with a weighty roller, which will press the earth close to the roots of the corn, and thereby prevent the sun and air from penetrating the ground, which will be of singular service in dry seasons; and this rolling of it before it stalks, will cause it to till out into a greater number of stalks; so that if the plants should be thin,

this will cause them to spread so as to fill the ground, and likewise to strengthen the stalks.

The time for cutting of Barley is, when the red colour of the ears is off, and the straw turns yellow, and the ears begin to hang down: in the north of England they always reap their Barley, and make it up in sheaves, as practised here for Wheat, by which method they do not lose near so much corn, and it is also more handy to stack; but this method cannot so well be practised where there are many weeds amongst the corn, which is too frequently the case in the rich lands near London, especially in moist seasons; therefore when this is the case, the Barley must lie on the swarth till all the weeds are dead; but as it is apt to sprout in wet weather, it must be shook up, and turned every fair day after rain to prevent it. When it is carried in, it should be thoroughly dry, otherwise if it be stacked wet, it will turn musty; or if too green, it is subject to burn in the mow. The common produce of Barley, is two and a half, or three quarters on an acre, but I have sometimes known six or seven quarters on an acre.

HORIZONTAL SHELTERS have, by some persons, been greatly recommended to preserve fruit-trees from blights; but with how little reason, or upon what slight experiments, every one who has ever made use of them will easily judge; especially those which are contrived by placing tiles in the wall at certain distances, nothing being more obvious, than that vegetables, when prevented from receiving the advantage of dews, rains, &c. those kindly benefits of heaven, grow weak, languid, and at last entirely decay: and since, from vast numbers of experiments which have been lately made, we find that trees imbibe great quantities of nourishment through the pores of their leaves and branches, whereby they are rendered vigorous and healthy, even in such seasons, and upon such soils, where one would think it impossible they should receive much nourishment from the earth; to deprive them of this advantage, is no less than destroying them; though perhaps, if the trees are vigorous, it may not be effected suddenly; but there will be very visible signs of decay on them daily, and a few years will put a period to their lives, as I have more than once observed, where such walls were built.

The only sort of these shelters which I have ever observed useful for fruit-trees, was made with two leaves of slit deal, joined over each other, and painted; this being fixed upon the top of the wall with pulleys, to draw up and down at pleasure, formed a sort of pent-house; which being let down in great rains, or cold nights, during the time that the trees were in flower, or the fruit was setting, proved serviceable; but then these shelters were removed away soon after the fruit was set, so that the trees might enjoy all the advantages of rain, dew, &c. in the summer, which is absolutely necessary, if we would have healthy trees or good fruit.

HORMINUM. Tourn. Inst. 178. tab. 82. Salvia. Lin. Gen. Plant. 36. Clary; in French, *Ormin*.

The CHARACTERS are,

The empalement of the flower is permanent, of one leaf, tubulous, and channelled, having two lips; the upper is broad, ending in three acute points; the under is shorter, ending in two points. The flower has one petal, divided into two lips; the upper is concave, compressed on the two sides, and incurved with a slight indenture at the point, the lower is broader and more indented. It hath two short stamens, situated in the tube of the flower, terminated by short prostrate summits, and two other which decay soon after the flowers open. In the bottom of the tube are four roundish germen, supporting a single style crowned by a bifid stigma, situated in the upper lip of the petal. The germen afterward becomes four seeds, lodged in the empalement.

This genus of plants is ranged in the first section of Tournefort's fourth class, which includes the herbs with a lip flower of one leaf, whose upper lip is forked, or shaped like a helmet. Dr. Linnæus has joined this genus, and also the *Sclarea* of Tournefort to the *Salvia*, including them all in that genus; but

H O R

but as there are many species of each genus, so it is better to keep them alunder, whereby their old titles, by which they have always been known in the shops and market will be retained, though there is no very essential difference in their characters.

The SPECIES are,

1. **HORMINUM** (*Verbenacea*) foliis sinuatis serratis, corollis calyce angustioribus acutis. *Clary with sinuated fringed leaves, and the petal of the flower narrower than the cup.* Horminum sylvestre lavendulae flore. C. B. P. 239. *Wild Clary with a Lavender flower.*
2. **HORMINUM** (*Lyrata*) foliis pinnato-sinuatis rugosis, calycibus corollâ longioribus. *Clary with wing-shaped sinuated leaves, which are rough, and the empalements longer than the petal of the flower.* Horminum folio querno. Volk. *Oak-leaved Clary.*
3. **HORMINUM** (*Verticillatum*) verticillis subnudis, stylo corollarum labio inferiore incumbente. *Clary with heart-shaped, crenated, indented leaves, naked whorls, and the style lying under the lip of the petal.* Horminum sylvestre latifolium verticillatum. C. B. P. 283. *Broad-leaved wild Clary, with flowers growing in whorls.*
4. **HORMINUM** (*Napifolium*) foliis radicalibus pinnato-incisis, caulinis cordatis crenatis, summis semiamplexicaulibus. *Clary, whose lower leaves are cut and winged, those on the stalks heart-shaped and crenated, and those on the top half embracing the stalks.* Horminum napi folio. Mor. Hort. R. Bluff. *Clary with a Nettle leaf.*
5. **HORMINUM** (*Sativum*) foliis obtusis crenatis, bracteis summis sterilibus majoribus coloratis. *Clary with obtuse crenated leaves, the bractee on the top of the stalks large, coloured, and barren.* Horminum comâ purpuro-violaceâ. J. B. 3. 309. *Clary with a purple Violet top.*

The first sort grows naturally on sandy and gravelly grounds, in many parts of England. This a perennial plant; the lower leaves grow upon pretty long foot-stalks, and are near four inches long and two broad; they are sinuated on their borders, and bluntly crenated; their surface is rugged and wrinkled; the stalks are a foot long, square, and inclining toward the ground; the leaves upon these are smaller, and crenated on their edges; the flowers grow in a whorled spike at the top of the stalk, generally with two shorter spikes, one on each side; the flowers are small and blue; these are scarce so long as their empalements; they have but one petal, which is divided into two lips, the upper being a little longer than the under, and almost shuts over it; there are but two perfect stamina in each flower, and four germen at the bottom, supporting a single style; the germen afterward become so many naked seeds, sitting in the empalement. It flowers in June and July, and the seeds ripen in August and September. This sort propagates itself in plenty, if the seeds are permitted to scatter, and requires no other culture but to keep the plants clean from weeds.

This is sometimes called *Oculus Christi*, from the supposed virtues of its seeds in clearing of the sight, which it does by its viscid covering; for when any thing happens to fall into the eye, if one of the seeds is put in at one corner, and the eye-lid kept close over it, moving the seed gently along the eye, whatever happens to be there will stick to the seed, and so be brought out. The virtues of this are supposed to be the same as the Garden Clary, but not quite so powerful. The second sort grows naturally in the south of France and Italy; the lower leaves are upward of four inches long, and not more than one broad, regularly sinuated on both sides, in form of a winged leaf; the stalks rise about the same height with the former, but all the leaves upon the stalks are sinuated in the same manner as the lower; the flowers are smaller than those of the first, but grow in whorled spikes like them. This is a perennial plant, which is very hardy, and will propagate itself in plenty by the scattered seeds. It is seldom kept in gardens but for the sake of variety.

The third sort is a perennial plant, which grows na-

H O S

turally in Austria and Bohemia. This sends out from the root a great number of heart-shaped leaves, which are sawed on their edges and deeply veined, standing upon pretty long foot-stalks which are hairy; the stalks arise from between these, which are square; and grow two feet and a half high, which are garnished with two heart-shaped leaves at each joint; whose base fits close to the stalks, half embracing them; the stalks at the two or three upper joints, put out on each side a long foot-stalk; these, and also the principal stalk, are garnished with whorls of small blue flowers, not much unlike those of the common sort, but larger; the spikes are more than a foot long, and toward the top the whorls are nearer together. It flowers in June, and the seeds ripen in August.

The fourth sort grows naturally in the south of France, and in Italy. This is also a perennial plant, which has some resemblance of the third, but the lower leaves of this are cut at their base to the midrib, into one or two pair of ears or lobes, which are but small, and are often at a distance from each other; the leaves are not sawed, but are bluntly indented; the stalks of this are slenderer, and do not grow so tall as those of the third, nor are the spikes of flowers so long. This flowers and seeds at the same time with the third.

Both sorts may be easily propagated by seeds, which, if sown in the spring on an open spot of ground, the plants will come up, and require no other care but to keep them clean from weeds, and allow them room to grow; for the plants should not be nearer than two feet apart, for they grow very large, and will last several years.

The fifth sort is an annual plant, which grows naturally in Spain; of this there are three varieties which are constant, one with purple tops, another with red tops, and a third with green tops. As they differ in nothing but the colour of their bractee on the top of the stalks, so I have not put them down as different species, though from more than thirty years cultivating them, I have not known them alter.

These plants have obtuse crenated leaves, shaped like those of the common red Sage; the stalks are square and grow erect, about a foot and a half high; their lower parts are garnished at each joint with two opposite leaves of the same shape, but gradually diminishing in size toward the top: the stalks are garnished upward with whorls of small flowers, and are terminated by clusters of small leaves, which in one are red, in another blue, and a third green, which make a pretty appearance, and are preserved in gardens for ornament. They flower in June and July, and their seeds ripen in the autumn.

The seeds of these are sown in the spring, in the places where they are designed to remain, and require no other care but to keep them clean from weeds, and thin them where they come up too close.

Garden Clary. See *SCALARIA*.

HORNEBEAM. See *CARPINUS*.

HORSE CHESTNUT. See *ESCUUS*.

HORSE DUNG is of great use to make hot-beds for the raising all sorts of early garden crops, as Cucumbers, Melons, Asparagus, Saladings, &c. for which purpose no other sort of Dung will do so well, this fermenting the strongest; and, if mixed with long litter, and sea-coal ashes in a due proportion, will continue its heat much longer than any other sort of Dung whatsoever; and afterwards when rotted, becomes an excellent manure for most sorts of lands, more especially for such as are of a cold nature; and for stiff clayey lands, when mixed with sea-coal ashes, and the cleansing of London streets, it will cause the parts to separate much sooner than any other compost will do; so that where it can be obtained in plenty, I would always recommend the use of it for such lands.

HOSE IN HOSE, a term used in gardening, to signify one tube or petal within another, as in the

H O T

Polyanthus, where there are in some varieties two petals.

HOT-BEDS are of general use in these northern parts of Europe, without which we could not enjoy so many of the products of warmer climes as we do now; nor could we have the tables furnished with the several products of the garden, during the winter and spring months, as they are at present in most parts of England, better than perhaps in any other country in Europe: for although we cannot boast of the clemency of our climate, yet England is better furnished with all sorts of esculent plants for the table, much earlier in the season, and in greater quantities, than in the gardens of our neighbours, which is owing to our skill in Hot-beds.

The ordinary Hot-beds which are commonly used in the kitchen-gardens, are made with new horse dung, in the following manner:

1st, There is a quantity of new horse dung from the stable (in which there should be part of the litter or straw which is commonly used in the stable, but not in too great proportion to the dung,) the quantity of this mixture must be according to the length of the bed intended; which, if early in the year, should not be less than one good load for each light; this dung should be thrown up in a heap, mixing therewith a few sea-coal ashes, some leaves of trees, and tan, which will be of service to continue the heat of the dung; it should remain six or seven days in this heap; then it should be turned over, and the parts well mixed together, and cast into a heap again, where it may continue five or six days longer, by which time it will have acquired a due heat; then in some well sheltered part of the garden, you must dig a trench in length and width, proportionable to the frames you intend it for; and if the ground be dry, about a foot deep; but if wet, not above six inches; then wheel the dung into the opening, observing to stir every part of it with a fork, and lay it exactly even and smooth thro' every part of the bed; as also to lay the bottom part of the heap (which is commonly free from litter) upon the surface of the bed; this will prevent the steam from rising so plentifully as it would otherwise do. To prevent this, and the heat from rising so violently as to burn the roots of whatever plants are put into the ground, it will be a very good way to spread a layer of neats dung all over the surface of the horse dung, which will prevent the mould from burning: if the bed is intended for Cucumbers or Melons, the earth should not be laid all over the bed at first, only a hill of earth should be first laid in the middle of each light on which the plants should be planted, and the remaining space should be filled up from time to time as the roots of the plants spread; but this is fully explained under those two articles. But if the hot-bed is intended for other plants, then after the bed is well prepared, it should be left two or three days for the steam to pass off, before the earth is laid upon the dung.

In the making of these hot-beds, it must be carefully observed to settle the dung close with a fork; and if it be full of long litter, it should be equally trod down close in every part, otherwise it will be subject to heat too violently, and consequently the heat will be much sooner spent, which is one of the greatest dangers these sort of beds may be liable to. During the first week or ten days after the bed is made, you should cover the glasses but slightly in the night, and in the day time carefully raise them to let out the steam, which is subject to rise very copiously while the dung is fresh; but as the heat abates, so the covering should be increased; otherwise the plants in the beds will be stunted in their growth, if not entirely destroyed. In order to remedy this evil, if the bed be very cold, you must put a pretty good quantity of new hot dung round the sides of it, which will add a fresh heat thereto, and cause it to continue a considerable time after; and as the spring advances, the sun will supply the loss of the dung's heat; but then it will be advisable to lay some mowings of Grass round

H O T

the sides of the bed, especially if the nights should prove cold, as it often happens in May, which is many times, even at that season, very hurtful to tender plants on Hot-beds.

But although the Hot-bed I have described is what the kitchen-gardeners commonly use, yet those made with tanners bark are much preferable, especially for all tender exotic plants or fruits, which require an even degree of warmth to be continued for several months, which is what cannot be effected by horse dung only. The manner of making these beds is as follows:

There must be a trench dug in the earth about three feet deep, if the ground be dry; but if wet, it must not be above a foot or six inches deep at most, and must be raised in proportion above ground, so as to admit of the tan being laid three feet thick. The length must be proportioned to the frames intended to cover it, but should never be less than eleven or twelve feet; but if it is twice that length it will be better, and the width not less than six, which is the least size of these beds for to continue the heat. This trench should be bricked up round the sides to the above-mentioned height of three feet, paving the bottom with bricks to prevent the earth mixing with the tan, and should be filled in the spring with fresh tanners bark (i. e. such as the tanners have lately drawn out of their vats, after they have used it for tanning leather) which should be laid in a round heap for a week or ten days before it is put into the trench, that the moisture may the better drain out of it, which, if detained in too great a quantity, will prevent its fermentation; then put it into the trench, and gently beat it down equally with a dung-fork; but it must not be trodden, which would also prevent its heating, by settling it too close; then you must put on the frame over the bed, covering it with the glasses, and in about ten days or a fortnight it will begin to heat; at which time you may plunge your pots of plants or seeds into it, observing not to tread down the bark in doing it.

A Bed thus prepared (if the bark be new and not ground too small) will continue in a good temper of warmth for two or three months; and when you find the heat decline, if you stir up the bark again pretty deep, and mix a load or two of fresh bark amongst the old, it will cause it to heat again, and preserve its warmth two or three months longer. There are many people who lay some hot horse dung in the bottom of the trench, under the bark, to cause it to heat; but this is what I would never practise, unless I wanted the bed sooner than the bark would heat of itself, and then I would put but a small quantity of dung at bottom, for that is subject to make it heat too violently, and will occasion its losing the heat sooner than ordinary; and there will never be any danger of the bark's heating if it be new, and not put into the trench too wet, though it may sometimes be a fortnight or more before it acquires a sufficient warmth, but then the heat will be more equal and lasting.

The frames which cover these Beds should be proportioned to the several plants they are designed to contain: for example, if they are to cover the Ananas or Pine-apple, the back part of the frame should be three feet and a half high, and the lower part fifteen inches, which will be a sufficient declivity to carry off the water, and the back side will be high enough to contain the large fruiting plants, and the lower side will be sufficient for the shortest plants; so that by placing them regularly according to their height, they will not only have an equal distance from the glasses, but also appear much handsomer to the sight. And although many people make their frames deeper than what I have allotted, yet I am fully persuaded, that where there is but height enough to contain the plants, without bruising their leaves, it is much better than to allow a larger space; for the deeper the frame is made, the less will be the heat of the air inclosed therein, there being no artificial warmth but what the bark affords, which will not heat a large space of air; and

as

as the Pine-apple requires to be constantly kept very warm, in order to ripen the fruit well, so it will be found upon trial, that the depth I have allowed will answer that purpose better than a greater.

But if the Bed be intended for taller plants, then the frame must be made in depth proportionable thereto; but if it be for sowing of seeds, the frame need not be above fourteen or sixteen inches high at the back, and seven inches deep in the front, by which means the heat will be much greater; and this is commonly the proportion allowed to the frames usually made use of in the kitchen-gardens. As to their length, that is generally according to the fancy of the owner; but they commonly contain three lights each, which is in the whole about eleven feet in length, though sometimes they are made to contain four lights; but this is too great a length for the boxes, for the frames thus made are not so handy to remove, as when they are shorter, and are more subject to decay at their corners. Some indeed have them to contain but two lights, which is very handy for raising Cucumber and Melon plants while young; but this is too short for a Bark-bed, as not allowing room for a proper quantity of bark to continue a warmth for any considerable time, as was before-mentioned; but for the other purposes, one or two such frames are very convenient for common Dung-beds.

As to those frames which are made very deep, it is much the better way to have them made to take asunder at the four corners, so that they may be removed with ease; otherwise it will be very difficult to take the frame off, when there is occasion to put in new bark, or take out the old. The manner of making these frames is generally known, or may be much better conceived by seeing them than can be expressed in writing, therefore I shall forbear saying any thing more on this head.

HOTTONIA. Boerh. Ind. alt. 1. p. 207. Lin. Gen. Plant. 203. Stratoites. Vaill. Act. Par. 1719. Water Violet.

The CHARACTERS are,

The flower is funnel-shaped; it has one petal, with a tube the length of the one-leaved empalement, but is cut above into five oblong oval segments, which spread open, and are indented at their extremity. It hath five short awl-shaped stamina standing on the tube of the petal, opposite to the cuts, terminated by oblong summits. In the center is situated a globular germen ending in a point, supporting a short slender style crowned by a globular stigma, which afterward becomes a capsule of the same form, with one cell, filled with globular seeds, sitting upon the empalement.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which includes the plants whose flowers have five stamina and one style.

We know but one SPECIES of this genus, viz.

HOTTONIA (*Palustris*.) Boerh. Ind. alt. 1. p. 207. Water Violet. *Millifolium aquaticum* five *viola aquatica caule nudo*. C. B. P. 141. *Water Milfoil, or Water Violet, with a naked stalk.*

This plant grows naturally in standing waters in many parts of England; the leaves which are for the most part immersed in the water, are finely winged and flat, like most of the sea plants; these extend pretty wide, and at the bottom have long fibrous roots, which strike into the mud; the flower-stalks rise five or six inches above the water; they are naked, and toward the top have two or three whorls of purple flowers, terminated by a small cluster of the same. These flowers have the appearance of those of the Stock-gilliflower, so make a pretty appearance on the surface of the water. The flowers appear in June.

It may be propagated in deep standing waters, by procuring its seeds, when they are ripe, from the places of their natural growth, which should be immediately dropped into the water where they are designed to grow, and the spring following they will appear; and

if they are not disturbed, they will soon propagate themselves in great plenty.

HUMIDITY is the quality commonly called moisture, or the power of wetting others, which quality some liquors and fluids are endowed with; and it differs very much from fluidity, in that it depends altogether on the congruity of the component particles of any liquor to the pores or surfaces of such particular bodies, as it is capable of adhering to.

Thus, quicksilver is not a moist liquor, in respect to our hands or clothes, and many other things it will not stick to; but it may be called a moist liquor, in respect to gold, lead, or tin, to the surfaces of which it will presently adhere.

Nay, water itself, that wets almost every thing, and is the great standard of Humidity, or moisture, is not capable of wetting every thing; for it stands, and runs easily off in globular drops, on the leaves of Cabbages, and many other plants; and will not wet the feathers of ducks, swans, and other water fowl.

And it is very plain, that it is only the texture that may cause the fluid to be humid; because neither quicksilver alone, nor bismuth, will stick upon glass; yet being mixed together, they will form a mass that will stick on it; as it is very well known in the fo-liating of looking-glasses, in which such a composition is used.

HUMULUS. See LUPULUS.

HURA. Lin. Gen. Plant. 965. Hura, or Sand-box-tree.

The CHARACTERS are,

It hath male and female flowers on the same plant. The male flowers have no petal, or scarce any empalement, but a column of stamina, which are joined at bottom to the style, forming a cylinder; these spread out at the top, and are terminated by single summits lying over each other. The female flowers have a swelling empalement of one leaf, with one tubulous petal; the roundish germen is situated in the bottom of the empalement, supporting a long cylindrical style, crowned by a large funnel-shaped stigma, which is a plain convex, divided into twelve equal obtuse parts. The germen afterward becomes an orbicular ligneous fruit, depressed at top and bottom, having twelve deep furrows, with so many cells, which open at the top with an elasticity, each containing one round flat seed.

This genus of plants is ranged in the ninth section of Linnæus's twenty-first class, intitled Monœcia Monodelphia, which includes those plants which have male and female flowers at separate distances in the same plant, whose stamina are joined to the style, forming one body.

We know but one SPECIES of this genus, viz.

HURA (*Crepitans*.) Hort. Cliff. 486. Sand-box-tree. *Hura Americana*, *Abutili Indici folio*. Hort. Amst. 2. 131. tab. 66. *American Hura with the leaf of the Indian Abutilon, commonly called in the West-Indies Sand-box-tree.*

This grows naturally in the Spanish West-Indies, from whence it has been introduced into the British colonies of America, where some of the plants are preserved by way of curiosity. It rises with a soft ligneous stem to the height of twenty-four feet, dividing into many branches, which abound with a milky juice, and have scars on their bark, where the leaves have fallen off. The branches are garnished with heart-shaped leaves; those which are the biggest are eleven inches long, and nine inches broad in the middle, indented on their edges, having a prominent midrib, with several transverse veins from that to the sides, which are alternate; these stand upon long slender foot-stalks. The male flowers come out from between the leaves, upon foot-stalks which are three inches long; they are formed into a close spike, or katkin, forming a column, lying over each other like the scales of fish. The female flowers are situated at a distance from the male; these have a swelling cylindrical empalement, out of which rises the petal of the flower, which hath a long funnel-shaped tube, spreading at the top,

top, where it is divided into twelve parts, which are reflexed. After the flower is past, the germen swells and becomes a round, compressed, ligneous capsule, having twelve deep furrows, each being a distinct cell, containing one large round compressed seed; when the pods are ripe, they burst with an elasticity, and throw out their seeds to a considerable distance.

It is propagated by seeds, which should be sown early in the spring, in pots filled with light rich earth, and plunged into a hot-bed of tanners bark. If the seeds are fresh, the plants will appear in about five or six weeks after the seeds are sown. As the plants will advance very fast, where due care is taken of them, so they should have a large share of fresh air admitted to them in warm weather, otherwise they will draw up too weak. When the plants are about two inches high, they should be transplanted each into a separate small pot filled with light rich earth, and plunged again into the hot-bed of tanners bark, being careful to shade them from the heat of the sun, until they have taken new root; after which time they must have free air admitted to them, by raising of the glasses in proportion to the warmth of the season, and should be frequently, but gently, watered. When the plants have filled these small pots with their roots, they must be shaken out of them, and their roots trimmed, and then placed in larger pots, which should be filled with the like rich earth, and plunged again into the hot-bed, where they should remain till Michaelmas, provided the plants have room, without touching of the glasses, at which time they must be removed into the bark-stove, and plunged in the warmest part thereof: during the winter season they must be sparingly watered, for as the plants have succulent stalks, much moisture will rot them; they must also be kept very warm, otherwise they will not live in this country. In summer they must have a large share of fresh air in warm weather, but they must not be removed into the open air, for they are too tender to live abroad in the warmest part of the year in this country.

This plant is now pretty common in the English gardens, where there are collections of tender plants preserved, some of which are grown to the height of twelve or fourteen feet, and many of them have produced flowers, but there has not been any of their fruit produced as yet in England.

As these plants have ample leaves, which are of a beautiful green colour, they afford an agreeable variety among other tender exotic plants in the stove; for where they are kept warm, and duly refreshed with water, they retain their leaves all the year in verdure.

The fruit of this plant is, by the inhabitants of the West-Indies, cut open on the side where the foot-stalk grew, and the seeds carefully taken out, after which the shells are used to contain sand for writing, which gave rise to the name of Sand-box. When these fruit are brought entire into England, it is very difficult to preserve them; for when the heat of the summer comes on, they usually burst with an explosion, and scatter their seeds about; and from the noise made by the ripe fruit, it was by Hernandez titled, *Arbor crepitans*.

HYACINTHUS. Tourn. Inst. R. H. 344. tab. 180. Lin. Gen. Plant. 427. Hyacinth; in French, *Jacinte*.

The CHARACTERS are,

The flower has no empalment. It has one bell-shaped petal, whose rim is cut into six parts, which are reflexed; and three nectariums on the point of the germen, with six short awl-shaped stamina, terminated by summits, which close together. In the center is situated a roundish three-cornered germen, having three furrows supporting a single style, crowned by an obtuse stigma. The germen afterward becomes a roundish three-cornered capsule, having three cells, which contain roundish seeds.

This genus of plants is ranged in the first section of Linnaeus's sixth class, intitled *Hexandria Monogy-*

nia, which includes those plants whose flowers have six stamina and but one style.

The SPECIES are,

1. **HYACINTHUS** (*Nonscriptus*) corollis campanulatis sexpartitis apice revolutis. Hort. Cliff. 125. *Hyacinth with a bell-shaped petal divided into six parts, which are reflexed at their tops.* Hyacinthus oblongo flore caeruleus major. C. B. P. 43. *Greater Hyacinth with an oblong blue flower*; and the Hyacinthus Anglicus. Ger. 99. *English Hyacinth, or Hare Bells.*
2. **HYACINTHUS** (*Serotinus*) corollarum exterioribus petalis subdistinctis, interioribus coadunatis. Lin. Sp. Plant. 453. *Hyacinth whose exterior part of the flower has distinct petals, but the interior joined.* Hyacinthus obsoleto flore. C. B. P. 44. *Hyacinth with a worn-out flower.*
3. **HYACINTHUS** (*Utrique Floribus*) corollis campanulatis sexpartitis, floribus utrinque dispositis. *Hyacinth with a bell-shaped petal which is divided into six parts, and flowers ranged on each side of the stalk.* Hyacinthus floribus campanulae utrinque dispositis. C. B. P. 44. *Hyacinth with bell-shaped flowers disposed on every side the stalk.*
4. **HYACINTHUS** (*Cernuus*) corollis campanulatis sexpartitis racemo cornuo. Lin. Sp. Plant. 217. *Hyacinth with bell-shaped petals divided into six parts, and a nodding branch of flowers.* Hyacinthus floribus campanulae, uno versu dispositis. C. B. P. 44. *Hyacinth with bell-shaped flowers ranged on one side the stalk.*
5. **HYACINTHUS** (*Aethylinum*) corollis campanulatis semisextidis basi cylindricis. Hort. Upsal. 58. *Hyacinth with bell-shaped petals cut half way into six parts, and a cylindrical base.* Hyacinthus oblongo flore minor. C. B. P. 44. *Lesser Hyacinth with an oblong blue flower.*
6. **HYACINTHUS** (*Orientalis*) corollis infundibuliformibus semisextidis basi ventricosis. Hort. Upsal. 85. *Hyacinth with a funnel-shaped petal cut half into six parts, and swelling at their base.* Hyacinthus Orientalis albus primus. C. B. P. 44. *Early White Eastern Hyacinth.*

The sorts here mentioned are all of them distinct species, of which there are several varieties, especially of the sixth, which have been cultivated with so much art, as to render some of them the most valuable flowers of the spring; in Holland the gardens abound with them, where the florists have raised so many varieties as to amount to some hundreds; and some of their flowers are so large, double, and finely coloured, as that their roots are valued at twenty or thirty pounds sterling each root; to enumerate these varieties here, would swell this work to very little purpose, as every year produces new kinds.

The first sort grows naturally in woods and near hedges, in lands which have lately been woods, in many parts of England, so is seldom admitted into gardens; but the poor people, who make it their business to gather the wild flowers of the fields and woods for nosegays, &c. bring great quantities of these in the spring to London, and sell them about the streets.

There is a variety of this with white flowers, which is kept in some gardens, which only differs in the colour of their flowers from the other.

The second sort is preserved in some few gardens for the sake of variety, but as it hath as little beauty as the first, so is seldom allowed a place in the flower-garden. The flowers of this are narrower than those of the first sort, and seem as if their petals were divided to the bottom, three of the outer segments being separated from the other, standing at a small distance from the three interior, but they are all joined at their base; when the flowers first appear, they are of a light blue colour, but before they decay, they fade to a worn-out purple colour. This flowers early in the spring, and grows naturally in Spain and Mauritania.

The third sort grows naturally in Spain and Italy; this hath blue flowers of the open spread bell-shape, which are divided into six segments almost to the bot-

tom, and are disposed on every side the stalk. The stalks rise about nine inches high, and when the roots are strong, the thyse of flowers is large. This flowers about the same time with the first sort, and was formerly preserved in gardens, but since there have been so many finer flowers raised from the seeds of the Eastern Hyacinths, these have been almost totally neglected, so that they are seldom seen but in old gardens. The fourth sort seems to be a variety of the first, the flowers being ranged for the most part upon one side of the stalk, and the top of the spike is always bent on one side. The flowers are of a blush Peach colour, and appear about the same time as the first sort. The fifth sort grows naturally in Spain; this hath a smaller flower than either of the former sorts, and comes earlier in the season. The petal is cut into six parts half the length, and is reflexed at the brim; the lower part is cylindrical, a little swelling at the base, and is of a deeper blue than either of the former. This was formerly called by the gardeners the Coventry blue Hyacinth.

The sixth sort is the Eastern Hyacinth, of which we formerly had no other varieties in the English gardens, but the single and double white and blue flowering; but from the seeds of these there were a few others raised in England; and also by the Flemish gardeners, who came over annually with their flower-roots to vend in England; but the gardeners in Holland have within the last fifty years raised so many fine varieties, as to render the former sorts of little or no value.

But those who are desirous to preserve any of the old sorts, need not be at much trouble about it, for their roots propagate in great plenty in any soil or situation, and will require no other care but to take up their roots every other or third year, soon after their leaves decay, and plant them again in autumn; for if they are permitted to remain longer in the ground, their roots will have multiplied to so great a degree, as to render their flowers very small and weak, so of little worth.

All the different sorts of Hyacinths are propagated by seeds or offsets from the old bulbs; the former method has been but little practised in England till very lately, but in Holland and Flanders it hath been followed for many years, whereby they have obtained a very great variety of the most beautiful flowers of this kind: and it is owing to the industry of the florists in those countries, that the lovers and delighters in gardening are so agreeably entertained, not only with the curious variety of this, but of most other bulbous rooted flowers, few other florists thinking it worth their trouble to wait four or five years for the flowers of a plant, which when produced, perhaps there might not be one in forty that may deserve to be preserved; but they did not consider that it was only the loss of the four or five first years after sowing, for if they continued sowing every year after they began, there would be a succession of flowers annually, which would constantly produce at least some sorts that might be different from what they had before seen; and new flowers being always the most valuable to skilful florists (provided they have good properties to recommend them) it would always be a sufficient recompence for their trouble and loss of time.

The method of raising these flowers from seed is as follows: having provided yourself with some good seed (which should be saved from either semi-double, or such single flowers as are large, and have good properties) you must have a parcel of square shallow boxes or pots, with holes in their bottoms to let off moisture, which must be filled with fresh light sandy soil, laying the surface very level; then sow your seeds thereon as equally as possible, covering it about half an inch thick with the same light earth; the time for this work is about the middle or latter end of August. These boxes, or pots, should be placed where they may enjoy the morning sun only until the latter end of September, at which time they should be removed into a warmer situation, and towards the end of October they should be placed under a common hot-bed frame, where they may remain during the winter and spring

months, that they may be protected from hard frosts; though they should be exposed to the open air when the weather is mild, by taking off the glasses. In the latter end of February or the beginning of March, the young plants will begin to appear above ground, at which time they must be carefully screened from frosts, otherwise they will be soon destroyed when they are so young; but you must never cover them at that season but in the night, or in very bad weather; for when the plants are come up, if they are close covered, they will draw up very tall and slender, and thereby prevent the growth of their roots. About the middle of April, if the weather proves good, you may remove the boxes out of the frame, placing them in a warm situation, observing, if the season be dry, to refresh them now and then gently with a little water, as also to keep them very clear from weeds, which would soon overspread the tender plants, and destroy them, if permitted to remain.

Towards the beginning of May these boxes should be removed into a cooler situation; for the heat of the sun at that season would be too great for these tender plants, causing their blades to decay much sooner than they would naturally do, if they were screened from its violence. In this shady situation they should remain during the heat of summer, observing to keep them constantly clear from weeds; but you must not place them under the dripping of trees, &c. nor should you give them any water after their blades are decayed, for that would infallibly rot the roots. About the latter end of August you should sift a little light rich earth over the surface of the boxes, and then remove them again into a warmer situation, and treat them, during the winter, spring, and summer months, as was before directed: and about the middle of August following you should prepare a bed of light rich sandy soil, in proportion to the quantity of your seedling plants; and having levelled the surface very even, you should take the earth from the boxes in which your plants were raised, into a sieve, in order to get out all the roots, which by this time, (if they have grown well) will be about the thickness of a small quill; these roots should be placed upon the bed at about two or three inches asunder, observing to set the bottom part of their roots downwards; then cover them over two inches thick with the same light earth; but as it will be impossible to get all the small roots out of the earth in the boxes, you should spread the earth upon another bed equally, and cover it over with light earth; by which method you will not lose any of the roots, be they ever so small.

These beds must be arched over with hoops, and in very hard frosty weather they must be covered with mats, &c. to protect them from frost; and in the spring, when the green leaves are above ground, if the weather should be very dry, you must refresh them with water; but do this sparingly, for nothing is more injurious to these bulbs than too great quantities of moisture. During the summer season you must constantly keep the beds clear from weeds; but after the blades are decayed, you must never give them any water; and in autumn you should stir the surface of the bed with a very short hand-fork, being exceeding careful not to thrust it so deep as to touch the roots, which, if hurt, are very subject to perish soon after. Then sift a little fresh, light, rich earth over the bed about an inch thick, or somewhat more, and in winter cover them again (as was before directed.) In this bed the roots may continue two years, observing to treat them, both in summer and winter, as before; then the third year the roots should be carefully taken up a little before their leaves decay, laying the roots horizontally in the ground to ripen for three weeks, after which they may be kept out of the ground till the end of August, when they should be planted into new beds prepared as before, placing them at the distance of six inches asunder; in these beds the roots may remain till they flower, during which time they should be treated as before, with this difference only, that instead of covering them with mats in the winter, the surface of the ground should be covered with tanners bark.

When their flowers begin to shew themselves, you should mark all such as appear to have good properties, by thrusting a small stick down by each root; which roots, at the time for taking them up, should be selected from the rest, and planted by themselves; though I would by no means advise the rejecting any of the other roots, until they have blown two years, before which you cannot be ascertained of their value. When the green leaves of these plants begin to decay, their roots must be taken up, and a bed of light earth, in a shady situation, should be raised into a ridge; the better to shoot off the moisture, the roots should be laid into the earth again in an horizontal position, leaving the green leaves hanging out of the ground from the roots, whereby the great moisture contained in their very succulent leaves and flower-stalks may be exhaled, and prevented from returning to the roots, which, when suffered so to do, is very often the cause of their rotting after they are out of the ground. In this ridge the roots should remain until the leaves are quite dried off, when they must be taken up, and after being cleared of all manner of filth, which would be hurtful to them, they must be laid up in boxes, where they may be preserved dry until September, which is the proper season for planting them again; the method of doing this shall be hereafter mentioned, when we treat of the management of old roots.

I shall now proceed to the culture of such Hyacinths as have either been obtained from Holland, or are of our own product from the seeds of such flowers as were very beautiful, and worthy to be preserved in collections of good flowers: and it hath been the want of skill in the management of these noble flowers, which has occasioned the ill success most people have had with them in England, whereby they have been neglected, supposing their roots to degenerate after they have flowered in England, which is a great mistake; for were the roots managed with the same art as hath been practised in Holland, I am fully convinced they would thrive near as well in England as there, or elsewhere, as I have experienced; for, from some hundreds of roots which I have received from Holland at two or three different times, I have had a very great increase of their roots, which were as large, and produced as many flowers upon their stems, as the same sorts generally do in Holland.

The soil in which these flowers succeed best, is a light, sandy, fresh, rich earth, which may be composed after the following manner: take half fresh earth from a common, or pasture land, which is chiefly of a sandy loam; this should be off the surface, and not taken above eight or nine inches deep at most; and if you take the turf, or green sward with it, it will still be better, provided you have time to let it rot before it is used; to this you should add a fourth part of sea-sand, and the other fourth part of rotten cow dung; mix these well together, and cast it into a heap, where it may remain until you use it, observing to turn it over once in three weeks or a month, that it may be well mixed. If this compost is made two years before it is used, it will be much the better; but if you are obliged to use it sooner, then it should be oftener turned, that the parts may the better unite.

This soil should be laid two feet deep on the beds which are designed for Hyacinths, and if you lay a little rotten cow dung, or tanners bark, at the bottom, which may be within reach of the fibres, but should by no means touch the bulb, it will be better. If the soil is very wet where these beds are made, you should raise them ten or twelve inches above the surface of the ground; but if it be dry, they need not be raised above three or four inches.

The manner of preparing the beds is as follows: First, take all the former old earth out of the bed to the depth you intend, which should be near three feet; then spread some rotten neats dung, or tan, in the bottom, about six inches thick, laying it very level; upon this you should lay the above-mentioned earth two feet thick, levelling it very even; then

score out the distances for the roots, which should be eight inches square, in strait rows each way; after which, place your roots exactly in the squares, observing to set the bottom part downward; then cover the roots six inches deep with the same prepared earth, being very careful in doing this not to displace any of the roots; and if the tops of these beds are made a little rounding, to shoot off the wet, it will be of service in moist ground, provided the middle of the beds are not made too high, which is a fault the other way.

The best season for planting these roots is the middle or latter end of September, according to the earliness or lateness of the season, or the weather when it happens; but I would advise you never to plant them when the ground is extreme dry, unless there be a prospect of some rain soon after; for if the weather should continue dry for a considerable time after, the roots will receive a mouldiness, which will certainly destroy them. The beds will require no farther care until the frost comes on very severe, at which time they should have some rotten tan spread over them, about four inches thick; and if the alleys on each side of the bed are filled up, either with rotten tan, dung, or sand, it will prevent the frost from penetrating the ground on each side to the roots, and secure them from being destroyed; but when the winters prove very severe, it will also be proper to have some Peas-haulm, Straw, or such like covering laid over them, which will keep out the frost better than mats; and lying hollow, will admit the air to the surface of the ground, and also permit the exhalations to pass off, whereby the earth will remain dry, and prevent the roots from rotting, which has often happened when the beds have been too close covered. But you must observe to take off this light covering whenever the weather is mild, and only let it continue on in very hard frosts; for where the beds are covered with tan or sea-coal ashes, no common frost can penetrate through, so the coverings are useless, except in very severe frost; for a small frost cannot injure the roots before the green leaves appear above ground, which is seldom before the beginning of February, at which time the beds must be arched over with hoops, that they may be covered either with mats, canvas, or some other light covering, to prevent the frost from injuring the buds as they arise above ground; but these coverings must be constantly taken off every day when the weather is mild, otherwise the flower-stems will be drawn up to a great height, and become very weak, and the foot-stalks of the flowers will be long and slender, and so rendered incapable of supporting the bells; which is a great disadvantage to the flowers, for one of their greatest beauties consists in the regular disposition of their bells. When these hoops are fixed over the beds, the rotten tan should be most of it taken off them; in doing of which, great care should be taken not to bruise or injure the leaves of the Hyacinths, which by that time will be breaking out of the ground with the flower-stem, therefore the tan should be removed by the hands; or if any instrument is made use of in the doing of it, there must be great caution how it is performed.

When the stems of the flowers are advanced to their height before the flowers are expanded, you should place a short stick down by each root, to which, with a wire formed into a hoop, the stem of the flowers should be fastened, to support them from falling; otherwise, when the bells are fully expanded, their weight will incline them to the ground, especially if they are not screened from the wind and rain.

During their season of flowering they should be covered in the heat of the day from the sun, as also from all heavy rains; but they should be permitted to receive all gentle showers, as also the morning and evening sun; but if the nights are frosty, they must be constantly defended therefrom. With this management you may continue your Hyacinths in beauty at least one whole month, and sometimes more, according to their strength, or the favourableness of the season.

When

When their flowers are quite decayed, and the tops of their leaves begin to change their colour, you must carefully raise the roots out of the ground with a narrow spade, or some other handy instrument; this is what the Dutch gardeners term lifting of them: in the doing of this, the instrument must be carefully thrust down by the side of the root, being careful not to bruise or injure it, as also to put it below the bottom of the root; then by the forcing of this instrument on one side, the fibres of the root are raised and separated from the ground. The design of this is, to prevent their receiving any more nourishment from the ground; for by imbibing too much moisture at this season, the roots frequently rot after they are taken up: about a fortnight after this operation the roots should be entirely taken out of the ground, and then carried to beds situated where the morning sun only shines upon them; the earth of the beds should be loose and raised into a sharp ridge, laying the roots into it in a horizontal position, with their leaves hanging out, by which means a great part of the moisture contained in their thick succulent stalks and leaves will evaporate; which, if it were permitted to return back to the roots, would cause them to rot and decay after they are taken up, which has been the general defect of most of the Hyacinths in England.

In this position the roots should remain until the green leaves are entirely decayed, which perhaps may be in three weeks time. This is what the Dutch gardeners term the ripening of their roots, because by this method the roots become firm, and the outer cover is smooth, and of a bright purple colour; whereas those roots which are permitted to remain undisturbed, till the leaves and stalks are quite decayed, will be large, spongy, and their outer coats will be of a pale colour; for the stems of many of these flowers are very large, and contain a great quantity of moisture, which, if suffered to return into the roots, will infallibly cause many of them to perish. After they are so ripened, you must take them out of the ground, and wipe them clean with a soft woollen cloth, taking off all the decayed parts of the leaves and fibres, putting them into open boxes where they may lie singly, and be exposed to the air, but they must be preserved carefully from moisture; nor should they be suffered to remain where the sun may shine upon them; in this manner they may be preserved out of the ground until September, which is the season for planting them again, at which time you must separate all the strong flowering roots, planting them in beds by themselves, that they may make an equal appearance in their flowers; but the offsets and smaller roots should be planted in another separate bed for one year, in which time they will acquire strength, and by the succeeding year will be as strong as the older roots.

The single and semi-double flowers should be planted also in a bed by themselves, where they should be carefully sheltered (as was directed before) from the frost, until the flowers are blown; at which time their covering should be entirely removed, and they suffered to receive the open air, but the flower-stalks should be supported with sticks; which, though the weather may soon deface the beauty of the flowers, yet is absolutely necessary to promote their seeding; and when the seeds are quite ripe, you must cut off the vessels and preserve them, with the seeds therein, until the season for sowing it. But you must observe, that after these flowers have produced seeds, they seldom flower so well again, at least not in two years after; so that the best method to obtain good seeds is, to plant new roots every year for that purpose. Although these roots are, by most persons, taken up every year, yet if the beds are well prepared for them, they may remain two years in the ground unremoved, and the roots will increase more the second year than the first, though the flowers are more liable to degenerate; therefore those who cultivate these for sale, take up their roots annually when

they are large and saleable; but the offsets and small roots, they usually leave two years in the ground.

There are some persons who let their Hyacinth roots remain three or four years unremoved, by which they have a much greater increase of roots, than when they are annually taken up; but the roots by this great increase are frequently degenerated, so as to produce single flowers; therefore I should advise the taking up of the roots every year, especially those of the most valuable kinds, which is the most certain method to preserve them in their greatest perfection, though the increase may not be so great; and if these roots are planted a fortnight or three weeks earlier in the autumn than is before directed, it will cause them to produce stronger flowers; and those roots which are annually removed, will be rounder and firmer than such as stand two years unremoved.

For the other sorts of Hyacinth, see MUSCARI and ORNITHOGALUM.

HYACINTHUS TUBEROSUS. See CRINUM and POLYANTHES.

HYDRANGEA. Gron. Flor. Virg. 50. Lin. Gen. Plant. 492. We have no English title for this genus.

The CHARACTERS are,

The flower hath a small permanent empalement of one leaf, indented in five parts, and five roundish petals which are equal, and larger than the empalement. It hath ten stamina which are alternately longer than the petal, terminated by roundish summits. Under the flower is situated a roundish germen, supporting two short styles standing apart, crowned by permanent obtuse stigmas. The germen afterward turns to a roundish capsule, crowned by the two horned stigmas, divided transversely into two cells, filled with small angular seeds.

This genus of plants is ranged in the second section of Linnaeus's tenth class, intitled Decandria Dygynia, which includes the plants whose flowers have ten stamina and two styles.

We have but one SPECIES of this genus, viz.

HYDRANGEA (Arborescens.) Gron. Flor. Virg. 50.

This plant grows naturally in North America, from whence it has been brought within a few years past to Europe, and is now preserved in gardens for the sake of variety more than its beauty. It hath a spreading fibrous root, from which is sent up many soft, pithy, ligneous stalks, which rise about three feet high, garnished at each joint with two oblong heart-shaped leaves placed opposite, standing upon foot-stalks about one inch long; the leaves are three inches long, and two broad near their base, sawed on their edges, and have many veins running from the midrib upward to their borders; they are of a light green, and fall away in the autumn; the flowers are produced at the top of the stalks, in form of a corymbus; they are white, composed of five petals, with ten stamina surrounding the style. These appear toward the end of July and in August, but seldom perfect their seeds in England.

This is easily propagated by parting of the roots; the best time for this is the latter end of October, which is also the best time to transplant them: the plants should have a moist soil, for they grow naturally in marshy places; they require no other culture but to keep them clear from weeds, and dig the ground between them every winter. The roots are perennial, and if in very severe frost the stalks are killed, they will put out new ones the following spring.

HYDRASTIS. See WARNERIA.

HYDROCOTYLE, [of ὕδωρ, water, and κοτύλη, a cavity; because this plant has a cavity in the leaves which contains water, and the plant grows in marshes.] Water Navelwort.

This plant grows in great plenty in moist places in most parts of England, and is never cultivated for use, so I shall pass it over with only naming it.

HYDROLAPATHUM. See RUMEX.

HYDROPHYLLON. Lin. Gen. Plant. 187. Hydrophyllon. Tourn. Inst. R. H. 81, tab. 16. Water Leaf.

The

The CHARACTERS are,

The flower has a permanent empalement of one leaf, cut into five segments which spread open. It hath one bell-shaped petal, which is divided into five parts, indented at their points; under each of these segments is fixed a nectarium, which is situated about the middle, and shut up lengthways by two lamellæ. It hath five stamina which are longer than the petal, terminated by oblong prostrate summits, and an oval-pointed germen, supporting an awl-shaped style the length of the stamina, crowned by a bifid spreading stigma. The germen afterward becomes a globular capsule with one cell, inclosing one large round seed.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which includes the plants whose flowers have five stamina and one style.

We know but one SPECIES of this genus; viz.

HYDROPHYLLON (*Virginianum*) foliis pinnatifidis. Lin. Sp. 208. Morini. Joncq. Hort. *Water Leaf with wing-pointed leaves.*

This plant grows naturally in many parts of North America, on moist spongy ground. The root of it is composed of many strong fleshy fibres, which spread wide on every side, from which arise many leaves with foot-stalks five or six inches long, which are jagged into three, five, or seven lobes, almost to the midrib; these are indented on their edges, and have several veins running from the midrib to the sides; they are of a lucid green, and in the spring have water standing on the cavities, from whence I suppose Morinus gave it the title of Water Leaf, and not from the plant growing in water, as Tournefort conjectures. The flowers rise with foot-stalks from the root, having one or two small leaves of the same shape with the lower; the flowers are produced in loose clusters hanging downward; they are of a dirty white and bell-shaped, so make no great figure. They appear in June, and the seeds sometimes ripen here in August.

This plant is very hardy in respect to cold, but it should be planted in a moist rich soil; for if it is planted in a dry warm soil, it will not live, unless it is constantly watered in dry weather. It may be propagated by parting of the roots, which should be done in autumn, that the plants may be well rooted before spring, for otherwise they will require a great deal of water. It requires a moist soil and shady situation.

HYDROPIPER, the common biting Arse-smart, which grows in great plenty in moist places near ditches sides almost every where.

HYDROSTATICS [*ὕδραστατική*, of *ὕδωρ*, water, and *σταῖναι*, of *στάς*, standing, of *ἵστημι*, I stand or stop; Hydrostatics being conceived as the doctrine of the æquilibrium of liquors,] or the doctrine of the gravitation of fluid; or it is that part of the mechanics which considers the weight or gravity of fluid bodies; particularly of water, and of solid bodies immersed therein.

To Hydrostatics belongs whatever relates to the gravities and æquilibria of liquors, with the art of weighing bodies in water, in order to estimate their specific gravities.

Of the use of this science in horticulture, the Rev. Dr. Hales, in his excellent Treatise of Vegetable Statics, has given many examples, by experiments, shewing the quantities of moisture imbibed and perspired by plants and trees, necessary to be known, in order to promote the business of vegetation.

Some of the most useful heads of this science are;

1. That the upper parts of all fluids press upon the lower.
2. That a lighter fluid may gravitate or press upon a heavier.
3. That if a body that is contiguous to the water, be altogether, or in part, lower than the upper surface of the water, the lower part of the body will be pressed upwards by the water which touches it beneath.

4. There needs only a competent weight of an external fluid, to account for the rising of water in pumps, &c.

5. If a body be placed under water, so that its uppermost surface lie parallel to the horizon, the direct pressure that it sustains is no more than that of a column of water, whose base is the horizontal superficies of the body, and its height the perpendicular depth of the water. And if the water which leans on the body be contained in pipes which are open at both ends, the pressure of the water is to be estimated by the weight of a pillar of water, the base of which is equal to the lower orifice of the pipe; and whose height is equal to a perpendicular, which reaches from thence to the top of the water, although the pipe should be much inclined any way, or though it should be ever so regularly shaped, and much broader in some other place than the bottom.

6. A body which is immersed in a fluid, sustains a natural pressure from the fluid, which also increases as the body is placed deeper beneath the surface of the fluid.

7. The reason why water ascends in siphons, and by which it flows through them, may be explained from the external pressure of some other fluid, without having recourse to the abhorrence of a vacuum.

8. The most solid body, which will sink by its own weight at the surface, yet if it be placed at a depth twenty times greater than that of its own thickness it will not sink, if its descent be not assisted by the incumbent water.

9. If a body which is specifically lighter than a fluid, be immersed in that fluid, it will rise with a force proportionable to the excess of gravity in that fluid.

10. If a body which is heavier than a fluid be immersed, it will sink with a force that is proportionable to the excess of its gravity.

11. If any vessel be filled with water, or any other liquor, the surface of which is capable of being even, it will continue so till disturbed by some other external cause.

12. When the fluids are pressed, they are pressed undiquaque, i. e. on all sides.

How far the knowledge of any of these properties of fluids may conduce to the philosophical improvement of gardening, and the business of vegetation, will be more clearly perceived when well considered by the ingenious artist, than being set forth by words.

HYGROMETER [*ὕγρομετρον*, of *ὕγρως*, moist, and *μέτρον*, measure, of *μετρέω*, to measure,] is a machine or instrument contrived to shew or measure, the moistness and driness of the air, according as it abounds with moist or dry vapours, and to measure and estimate the quantity of such moistness and driness.

There are divers kinds of Hygrometers; for whatever body either swells or shrinks by driness or moisture, is capable of being formed into an Hygrometer; such are the woods of most kinds, particularly Ash, Deal, Poplar, &c. such also is a cord, catgut, &c.

Stretch a hempen cord or fiddle-string along a wall, bringing it over a truckle or pulley; and to the other end tie a weight, unto which fit a style or index; on the same wall fit a plate of metal, divided into any number of equal parts, and the Hygrometer is complete.

For it is a matter of undoubted observation, that moisture sensibly shortens the length of cords and strings; and that as the moisture evaporates, they return to their former length, and the like may be said of a fiddle-string.

The weight therefore, in the present case, upon an increase of the moisture of the air, will ascend, and upon a diminution of the same will descend.

Hence, as the index will shew the spaces of ascent and descent, and those spaces are equal to the increments and decrements of the length of the cord or gut, the instrument will discover whether the air be more or less humid now, than it was at another given time.

The

The ordinary contrivance with whip-cord is one of the easiest, for that will infallibly shorten and lengthen as the air grows moister and drier.

Some recommend a cat-gut as the best, which may be a yard in length suspended, having a plumbet or piece of lead, with an index or pointer hanging at the lower end, by means of which the cat-gut will twist or untwist as the air dries or moistens, and shorten and lengthen so as to raise and sink the plumbet with the index, and this index will point out the degree sought for.

The weight of this lead or plumbet, should be about two ounces.

Some persons who approve a fine whip-cord instead of cat-gut, use a greater weight of lead; the twisting and untwisting of the cat-gut or whip-cord, will make the lead with the index turn round, as well as rise and fall. The degrees may be made upon an open screw of brass within, with which the plumbet and index has its motion.

When you are provided with a barometer and Hygrometer, compare the motions of the one with the other, in order to judge what proportion the rise or fall of the quicksilver in the barometer bears to the twisting of the cat-gut or whip-cord; the degrees of which motion may be observed by the index or pointer of the Hygrometer; and at the same time both these must be compared with the rising and falling of the spirit in a thermometer, to know what degree of heat or cold attends every different change of weather.

HYGROSCOPE [of ὑγρὸς, moist, and σκοπεῖν, to view or consider,] a machine the same as the hygrometer, and for the same uses.

These instruments are of good use in conservatories, for measuring or shewing the dampness or driness of them in the winter season.

HYMENÆA Lin. Gen. Plant. 512. Courbaril. Plum. Nov. Gen. 49. tab. 14. Locust-tree.

The CHARACTERS are,

The outward involucre of the flower is divided into two parts, the inward is of one leaf, indented in five parts; the flower hath five petals, which are equal in size, and spread open. It hath ten declining stamina, which are short, terminated by oblong summits. In the center is situated an oblong germen, supporting a declining style, crowned by an acute stigma; the germen afterward becomes a large oblong pod, with a thick ligneous shell, divided into several partitions transversely, in each of which is lodged one compressed large seed, surrounded with a farinaceous pulp.

This genus of plants is ranged in the first section of Linnæus's tenth class, intitled Decandria Monogynia, which includes the plants whose flowers have ten stamina and one style.

We know but one SPECIES of this genus, viz.

HYMENÆA (Courbaril.) Hort. Cliff. 484. Locust-tree. Courbaril bifolia, flore pyramidato. Plum. Nov. Gen. 49. Two-leaved Courbaril with a pyramidal flower, commonly called Locust-tree in America.

This is a very large spreading tree in the West-Indies, where it grows in great plenty: it hath a large stem, covered with a russet bark, which divides into many spreading branches, garnished with smooth stiff leaves, which stand by pairs, their base joining at the foot-stalk, to which they stand oblique, one side being much broader than the other, the two outer sides being rounded, and their inside strait, so that they resemble a pair of sheep-shears; they are pointed at the top, and stand alternately on the stalk. The flowers are produced in loose spikes at the end of the branches, some of the short ligneous foot-stalks supporting two, and others three flowers, which are composed of five yellow petals striped with purple; the petals are short and spread open; the stamina are much longer, and of a purplish colour; these flowers are succeeded by thick, fleshy, brown pods, shaped like those of the Garden Bean; they are six inches long, and two inches and a half broad, of a purplish brown colour, and a ligneous consistence, with a large su-

ture on both edges; these contain three or four roundish compressed seeds, divided by transverse partitions.

The wood of this tree is esteemed as good timber in the West-Indies, and it yields a fine clear resin which is called gum anime in the shops, which makes an excellent varnish.

It is easily raised from the seeds if they are fresh; these must be sown in pots, and plunged into a hot-bed of tanners bark: there should be but one seed put into each pot, or if there is more, when the plants appear, they should be all drawn out to one soon after they come up, before their roots entangle, when it will be hazardous doing it; for if great care is not taken, the plant intended to be left may be drawn out with the other. As the roots of this plant are but slender, so they are very difficult to transplant; for unless a ball of earth is preserved to their roots, they seldom survive their removal, therefore they must be seldom transplanted from one pot to another. The plants must constantly remain in the tan-bed in the stove, and should be treated in the same way with other tender plants of the same country, giving but little water to them, especially in the winter. When these plants first appear, they make considerable progress for two or three months, after which time they are at a stand perhaps a whole year without shooting, being in their growth very like the Anacardium, or Cashew Nut, so is very difficult to preserve long in this country.

HYOSCYAMUS Tourn. Inst. R. H. 117. tab. 42. Lin. Gen. Plant. 218. [of ὄστρον, a swine, and κνέμιον, a Bean, q. d. Hog's-bean,] Henbane; in French, Jusquaime.

The CHARACTERS are,

The flower has a cylindrical empalement of one leaf, which is permanent, swelling at the bottom, and cut into five acute segments at the top. It hath one funnel-shaped petal, with a short cylindrical tube, and an erect spreading rim, cut into five obtuse parts, one being larger than the others; it hath five inclined stamina, terminated by roundish summits. In the center is situated a roundish germen, supporting a slender style, crowned by a round stigma. The germen afterward becomes an oval obtuse capsule sitting in the empalement, divided in two cells by an intermediate partition, opening with a lid at the top, to let out the many small seeds which adhere to the partition.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, in which he includes those plants whose flowers have five stamina and one style.

The SPECIES are,

1. **HYOSCYAMUS** (Niger) foliis amplexicaulibus sinuatis, floribus sessilibus. Hort. Cliff. 56. Henbane with sinuated leaves embracing the stalks, and sessile flowers. Hyoscyamus vulgaris, vel niger. C. B. P. Common Black Henbane.
2. **HYOSCYAMUS** (Major) foliis petiolatis, floribus pedunculatis terminalibus. Henbane with leaves having foot-stalks, and flowers with foot-stalks terminating the branches. Hyoscyamus major, albo similis, umbilico floris atro-purpureo. T. Cor. Great Henbane like the white, but with a dark purple bottom to the flower.
3. **HYOSCYAMUS** (Albus) foliis petiolatis, floribus sessilibus. Hort. Upsal. 56. Henbane with leaves having foot-stalks, and flowers sitting close to the branches. Hyoscyamus major, albo similis, umbilico floris virenti. Jussieu. Greater Henbane like the white, with a green bottom to the flower.
4. **HYOSCYAMUS** (Minor) foliis petiolatis, floribus solitariis lateralibus. Henbane with leaves having foot-stalks, and flowers proceeding singly from the sides of the branches. Hyoscyamus minor albo similis, umbilico floris atro-purpureo. Tourn. Cor. 5. Smaller Henbane like the white, with a dark purple bottom to the flower.
5. **HYOSCYAMUS** (Reticulatis) foliis caulinis petiolatis cordatis sinuatis acutis; floribus integerrimis, corollis ventricosis. Lin. Sp. 257. Henbane with heart-shaped, sinuated,

finuated, acute leaves upon foot-stalks, and entire swollen flowers. Hyoscyamus rubello flore. C. B. P. *Henbane with a reddish coloured flower.*

6. **HYOSCYAMUS** (*Aureus*) foliis petiolatis eroso-dentatis acutis, floribus pedunculatis fructibus pendulis. Lin. Sp. 257. *Henbane with acute indented leaves standing on foot-stalks, the flower having foot-stalks, and the fruit hanging.* Hyoscyamus Creticus luteus major. C. B. P. *Greater yellow Henbane of Candia.*
7. **HYOSCYAMUS** (*Puillus*) foliis lanceolatis dentatis, floralibus inferioribus binis, calycibus spinosis. Hort. Upsal. 44. *Henbane with spear-shaped indented leaves, and a prickly empalement.* Hyoscyamus pusillus aureus Americanus, antirrhini foliis glabris. Pluk. Alm. 188. tab. 37. fol. 5. *Low, golden, American Henbane, with a smooth Snapdragon leaf.*

The first of these sorts is very common in England, growing upon the sides of banks and old dunghills almost every where. It is a biennial plant with long fleshy roots, which strike deep into the ground, sending out several large soft leaves, which are deeply flashed on their edges, and spread on the ground; the following spring the stalks come out, which rise about two feet high, garnished with leaves of the same shape, but smaller, which embrace the stalks with their base; the upper part of the stalk is garnished with flowers standing on one side in a double row, sitting close to the stalks alternately; these are of a dark purplish colour with a black bottom, and are succeeded by roundish capsules, sitting within the empalement; these open with a lid at the top, and have two cells filled with small irregular seeds. This is a very poisonous plant, and should be rooted out in all places where children are suffered to come; for in the year 1729, there were three children poisoned with eating the seeds of this plant, near Tottenham-court; two of which slept two days and two nights before they could be awakened, and were with difficulty recovered; but the third being older and stronger, escaped better.

The roots of this plant are used for anodyne necklaces to hang about children's necks, being cut to pieces and strung like beads, to prevent fits and cause an easy breeding of their teeth, but they are very dangerous to use inwardly. For some years past there was a mixture of these roots brought over with Gentian, and used as such, which was attended with very bad effects, as hath been mentioned under the article of Gentian, so I shall not repeat it here.

The second sort grows naturally in the islands of the Archipelago. This hath rounder leaves, which are obtusely situated upon their borders, and stand upon foot-stalks; the stalks branch more than those of the first, and the flowers grow in clusters toward the end of the branches, standing upon short foot-stalks; they are of a pale yellow colour, with very dark purple bottoms.

The third sort is much like the second, but the flowers are in larger bunches, sitting very close on the ends of the branches; they are of a greenish yellow colour, with green bottoms. It grows naturally in the warm parts of Europe, and is the sort whose seeds should be used in medicine, being the white Henbane of the shops.

The fourth sort was brought from the Levant by Dr. Tournefort. This hath a smaller stalk than either of the former, whose joints are further distant; the leaves are roundish, and deeply indented in obtuse segments, standing upon pretty long foot-stalks; the flowers come out singly from the side of the stalks, at a good distance from each other; they are of a yellow colour with dark bottoms.

The fifth sort grows naturally in Syria; this rises with a branching stalk two feet high, garnished with long spear-shaped leaves having foot-stalks; the lower leaves are regularly cut on both sides into acute segments which are opposite, so are shaped like the winged leaves, but the upper leaves are entire; the flowers grow at the end of the stalks in bunches; they are of a worn-out red colour, and shaped like

those of the common sort, but their tubes are swollen.

All these are biennial plants, which perish soon after they have perfected their seeds. They flower in June and July, and their seeds ripen in the autumn, which, if permitted to scatter, will produce plenty of the plants the following spring; or if the seeds are sown at that season, they will succeed much better than in the spring; for when they are sown in spring, the plants seldom come up the same year. They are all hardy except the fifth sort, and require no other culture but to keep them clean from weeds, and thin the plants where they are too close. The fifth sort should have a warm situation and a dry soil, in which it will live much better through the winter than in rich ground.

The sixth sort grows naturally in Candia; this is a perennial plant with weak stalks, which require a support; the leaves are roundish, and acutely indented on their edges, standing upon pretty long foot-stalks; the flowers come out at each joint of the stalk; they are large, of a bright yellow, with a dark purple bottom; the style of this sort is much longer than the petal. It flowers most part of summer, and sometimes ripens seeds in the autumn. If these seeds are sown in pots as soon as they are ripe, and placed under a hot-bed frame in winter, the plants will come up in the spring; but if they are kept out of the ground till spring, they rarely succeed. This sort will continue several years, if they are kept in pots and sheltered in winter, for they will not live in the open air at that season, but it only requires to be protected from frost; therefore if these plants are placed under a common hot-bed in winter, where they may enjoy as much free air as possible in mild weather, they will thrive better than when they are more tenderly treated. This sort may be easily propagated by cuttings, which, if planted in a shady border during any of the summer months, will take root in a month or six weeks, and may be afterward planted in pots, and treated like the old plants.

HYPECOM. Tourn. Inst. R. H. 230. tab. 115. *Hypecoum*; Lin. Gen. Plant. 157. We have no English name for this plant.

The CHARACTERS are,

The empalement of the flower is composed of two small oval leaves, which are opposite and erect. The flower hath four petals; the two outer which are opposite, are broad, and divided into three obtuse lobes; the two other which are alternate, are cut into three parts at their points. It hath four stamina situated between the petals, which are terminated by oblong summits. In the center is placed an oblong cylindrical germen, supporting two short styles, crowned by acute stigma. The germen afterward becomes a long, compressed, jointed pod, which is incurved, with one roundish compressed seed in each joint.

This genus of plants is ranged in the second section of Linnæus's fourth class, which contains the plants whose flowers have four stamina and two styles.

The SPECIES are,

1. **HYPECOM** (*Procumbens*) filiquis arcuatis compressis articulatis. Hort. Upsal. 31. *Hypecoum with compressed jointed pods bent inward.* Hypecoum latiore folio. Tourn. *Broad-leaved Hypecoum.*
2. **HYPECOM** (*Pendulum*) filiquis cernuis teretibus cylindricis. Hort. Upsal. 31. *Hypecoum with taper, cylindrical, nodding pods.* Hypecoum tenuiore folio. Tourn. *Narrow-leaved Hypecoum.*
3. **HYPECOM** (*Erectum*) filiquis erectis teretibus torulosis. Hort. Upsal. 32. *Hypecoum with taper, erect, wreathed pods.* Hypecoum filiquis erectis teretibus. Amm. Ruth. 58. *Hypecoum with erect taper pods.*

The first sort hath many wing-pointed leaves of a grayish colour, which spread near the ground, and slender branching stalks, which lie prostrate on the surface of the ground; these are naked below, and at the top are garnished with two or three small leaves of the same shape and colour with the under ones; from between these leaves come out the foot-stalks of the flower, each sustaining one yellow flower with four petals,

petals, and a pointal stretched out beyond the petals, which afterward turns to a jointed compressed pod about three inches long, which bends inward like a bow, having one roundish compressed seed in each joint. This flowers in June and July, and the seeds ripen in August.

The second sort hath slender stalks which stand more erect, and the segments of the leaves are longer and much narrower than those of the first; the flowers are smaller, and come out at the division of the branches; these are succeeded by narrow taper pods, which hang downward. It flowers and seeds at the same time with the first.

The third sort grows in the east; Dr. Amman received the seeds from Dauria, and I received the seeds from Istria, where it was found growing naturally. This hath much the appearance of the second sort in leaf and flower, but the pods grow erect, and are wreathed and twisted about. It flowers and seeds at the same time with the others.

These plants are all of them annual, so their seeds should be sown soon after they are ripe, otherwise it will be a year before the plants will appear, on a bed of light fresh earth where they are to remain, for they seldom succeed if they are transplanted. When the plants are come up, they should be carefully cleared from weeds; and where the plants are too close, they must be thinned, leaving them about six or eight inches apart; after this they will require no other culture, but to keep them constantly clear from weeds. In June these plants will flower, and their seeds will be ripe in August.

When the seeds are sown in the spring, and the season proves dry, the seeds will not grow the first year; but if the ground is kept clear from weeds and not disturbed, the plants will come up the following spring. I have known the seeds of these plants remain in the ground two years, and the plants have come up the third spring very well; so that it will be very proper to sow some of the seeds in autumn, soon after they are ripe, in a warm border, where the plants may come up early the following spring; and these will be stronger, and more likely to perfect seeds, than those sown in the spring, by which method the kinds may be preserved.

If the seeds of these plants are permitted to scatter, the plants will come up the following spring without any care; and if they are treated in the same way as the others, they will thrive equally; but when the seeds are sown in the spring, they should be taken out of the pods, and divested of their fungous covering, which adheres close to them, so prevents their growing, till that is rotted and decayed.

These plants are seldom propagated but by those who are curious in botany, though for the sake of variety they may have a place in large gardens, because they require very little trouble to cultivate them; and as they take up but little room, so they may be intermixed with other small annual plants in large borders, where they will make a pretty appearance.

The juice of these plants is of a yellow colour, resembling that of Celandine, and is affirmed by some eminent physicians to have the same effect as opium.

HYPERICUM. Tourn. Inst. R. H. 254. tab. 131. Lin. Gen. Plant. 808. St. Johnswort; in French, *Millepertuis*.

The CHARACTERS are,

The flower hath a permanent empalement, divided into five oval concave segments; it hath five oblong oval petals which spread open, and a great number of hairy stamina, which are joined at their base in three or five distinct bodies, terminated by small summits. It hath in the center a roundish germen, supporting one, three, or five styles, the same length of the stamina, crowned by single stigmas. The germen afterward becomes a roundish capsule, having the same number of cells as there are styles in the flower, which are filled with oblong seeds.

This genus of plants is ranged in the third section of Linnæus's eighteenth class, intitled Polyadelphia

Polygynia, which contains the plants whose flowers have many stamina joined in distinct bodies, and several styles.

The SPECIES are,

1. **HYPERICUM** (*Perfoliatum*) floribus trigynis, caule ancipiti, foliis obtusis pellucido-punctatis. Hort. Cliff. 383. St. Johnswort with three styles to the flower, and obtuse leaves having pellucid punctures. *Hypericum vulgare*. C. B. P. 279. Common St. Johnswort.
2. **HYPERICUM** (*Quadrangulum*) floribus trigynis, caule quadrato herbaceo. Hort. Cliff. 380. St. Johnswort with three styles to the flowers, and a square herbaceous stalk. *Hypericum Ascyron dictum*, caule quadrangulo. J. B. 3. p. 382. St. Johnswort with a square stalk, commonly called St. Peterwort.
3. **HYPERICUM** (*Hircinum*) floribus trigynis, staminibus corollâ longioribus, caule fruticoso ancipiti. Hort. Cliff. 331. St. Johnswort with three styles to the flower, stamina longer than the petals, and a shrubby stalk with two sides. *Hypericum foetidum frutescens*. Tourn. 255. Stinking shrubby St. Johnswort.
4. **HYPERICUM** floribus trigynis, calycibus obtusis, staminibus corollâ longioribus caule fruticoso. Hort. Cliff. 381. St. Johnswort with three styles to the flower, obtuse empalements, stamina longer than the petals, and a shrubby stalk. *Hypericum frutescens Canariense multiflorum*. Hort. Amst. 2. p. 135. Shrubby St. Johnswort from the Canaries, having many flowers.
5. **HYPERICUM** (*Olympicum*) floribus trigynis, calycibus acutis, staminibus corollâ brevioribus, caule fruticoso. Hort. Cliff. 380. St. Johnswort with three styles to the flower, acute empalements, stamina shorter than the petals, and a shrubby stalk. *Hypericum Orientale*, flore magno. T. Cor. 19. Eastern St. Johnswort, with a large flower.
6. **HYPERICUM** (*Inodorum*) floribus trigynis, calycibus obtusis, staminibus corollâ longioribus, capsulis coloratis, caule fruticoso. St. Johnswort with three styles to the flower, obtuse empalements, stamina longer than the petals, coloured seed-vessels, and a shrubby stalk. *Hypericum Orientale*, foetido simile, sed inodorum. Tourn. Cor. 19. Eastern St. Johnswort, like the stinking kind, but without smell.
7. **HYPERICUM** (*Ascyron*) floribus pentagynis, caule tetragono herbaceo simpliciter, foliis lævibus integerrimis. Hort. Upsal. 236. St. Johnswort with five styles to the flower, a square, single, herbaceous stalk, and smooth entire leaves. *Ascyron magno flore*. C. B. P. 280. Tuscan with a large flower.
8. **HYPERICUM** (*Balearicum*) floribus pentagynis, caule fruticoso, foliis ramisque cicatrifatis. Lin. Sp. Plant. 783. St. Johnswort with five styles to the flower, a shrubby stalk, and scarified leaves and branches. *Ascyron Balearicum*, frutescens, maximo flore luteo, foliis minoribus, subtus verrucosis salvad. Boerh. Ind. alt. 1. 242. Shrubby Balearick St. Peterwort with a large yellow flower, and smaller leaves warted on their under side.
9. **HYPERICUM** (*Androsæmum*) floribus trigynis pericarpis baccatis, caule fruticoso ancipiti. Hort. Upsal. 237. St. Johnswort with three styles to the flower, a fleshy seed-vessel, and a shrubby stalk with two sides. *Androsæmum maximum frutescens*. C. B. P. 280. Common Tuscan, or Park-leaves.
10. **HYPERICUM** (*Bartramium*) floribus pentagynis calycibus obtusis, staminibus corollâ æquantibus, caule erecto herbaceo. St. Johnswort with five styles to the flower, obtuse empalements, stamina equalling the petals, and an erect herbaceous stalk.
11. **HYPERICUM** (*Monogynum*) floribus monogynis, staminibus corollâ longioribus, calycibus coloratis, caule fruticoso. St. Johnswort with one style to the flowers, stamina longer than the petals, coloured empalements, and a shrubby stalk.

There are some other species of this genus, which are preserved in botanic gardens for the sake of variety, but as they are seldom admitted into other gardens, I have not enumerated them here, lest the work should swell too large.

The

The first and second sorts are both very common plants, growing in the fields in most parts of England; the first is used in medicine, but the second is of no use; these are rarely propagated in gardens, but I chuse to mention them, in order to introduce the other sorts, which deserve a place in every good garden.

The first sort hath a perennial root, from which arise several round stalks a foot and a half high, dividing into many small branches, which are garnished at each joint with two small oblong leaves, standing opposite; without foot-stalks; the branches also come out opposite. The leaves have many pellucid spots in them, which appear like so many holes when held up against the light. The flowers are numerous on the tops of the branches, standing on slender foot-stalks; they are composed of five oval petals, of a yellow colour, with a great number of stamina, not quite so long as the petals, terminated by roundish summits. In the center is situated a roundish germen, supporting three styles, crowned by single stigmas. The germen afterward becomes an oblong angular capsule, with three cells, filled with small brown seeds. It flowers in June and July, and the seeds ripen in autumn. The root is perennial, so will continue many years; and if the seeds are permitted to scatter, the plants will come up in too great plenty, so as to be very troublesome weeds. The leaves and flowers of this are used in medicine; it is esteemed an excellent vulnerary plant, and of great service in wounds, bruises, and contusions: there is a compound oil made from this plant, which is of great use in the foregoing accidents. From the stamina of the flower is expressed a red juice, which is sometimes used in colouring, but fades very soon.

The second sort hath square stalks, which rise about the same height with the first, but do not branch so much. The leaves are shorter and broader than those of the first, and have no pellucid spots. The flowers sit upon short foot-stalks at the end of the branches, which are shaped like those of the other. This flowers and seeds at the same time with the other, and will propagate in as great plenty if the seeds are permitted to scatter.

The third sort grows naturally in Sicily, Spain, and Portugal; this rises with shrubby stalks about three feet high, sending out small branches at each joint opposite, which are garnished with oblong oval leaves, placed by pairs, sitting close to the stalks, which have a rank smell like a goat. The flowers are produced in clusters at the end of the branches; they are composed of five oval yellow petals, with a great number of stamina which are longer than the petals, and three styles which are longer than the stamina. The germen which supports these, afterward becomes an oval capsule with three cells, filled with small seeds. It flowers in June, July, and August, and the seeds ripen in autumn.

The fourth sort grows naturally in the Canary Islands, so was formerly preserved in green-houses during the winter season, but is found to be hardy enough to resist the greatest cold of this country, so is now cultivated in the nurseries as a flowering shrub; this rises with a shrubby stalk six or seven feet high, dividing into branches upward, which are garnished with oblong leaves, set by pairs close to the branches. The leaves of this have also a strong odour, but not quite so bad as the former. The flowers are produced at the end of the stalks in clusters, and are very like those of the former sort, having a great number of stamina which are longer than the petals; this flowers at the same time with the former, and perfects its seeds in autumn. Both these plants have a very strong odour like that of a goat; so that where the plants grow in large quantities, the scent is carried by the wind to a great distance; or, if the leaves are handled, they emit the same odour.

These two sorts are propagated by suckers, which are plentifully sent forth from the old plants. The best season for taking off the suckers is in March, just

before they begin to shoot; they should be planted in a light dry soil, in which they will endure the severest cold of our climate very well. They may also be propagated by cuttings, which should be planted at the same season; or by seeds, which must be sown in August or September, which is as soon as they are ripe; for if they are kept till spring, few of them will grow; but as they multiply so fast by suckers, the other methods of propagating them are seldom practised in England. The fifth sort grows naturally on Mount Olympus, where it was discovered by Sir George Wheeler, who sent the seeds to the Oxford garden; this rises with many upright ligneous stalks about a foot high, garnished with small spear-shaped leaves, sitting close to the stalks opposite. The flowers are produced at the top of the stalks, three or four together; they are composed of five oblong petals, of a bright yellow colour, with a great number of stamina, which are of unequal lengths, some being longer, and others shorter than the petals, terminated by small roundish summits. In the center is situated an oval germen, supporting three slender styles, which are longer than the stamina. The germen afterward becomes an oval capsule with three cells, filled with small seeds. This flowers in July and August, and in warm seasons ripens its seeds in autumn.

This plant is usually propagated by parting of the roots, because the seeds seldom ripen in this country; the best time for doing of this is in September, that the plants may have time to get root before winter; this will live in the open air, if it is planted in a warm situation and a dry soil, but it will be proper to keep a plant or two in pots, to be sheltered under a frame in winter, lest in very severe winters, those in the open air should be destroyed. If this is propagated by seeds, they should be sown soon after they are ripe, in pots filled with light earth, and placed under a frame in the winter, to shelter them from frost, and in the spring the plants will appear; when these are fit to remove, some of them may be planted in a warm border, and others in pots, and treated in the same way as the old plants.

The sixth sort rises with a shrubby stalk seven or eight feet high, with a reddish bark, and sends out many smaller branches, garnished with oval heart-shaped leaves, whose base sits close to the stalks; they are placed opposite. The flowers are produced at the end of the stalks in clusters; they are smaller than those of the third sort, and have obtuse em-palements. The stamina are longer than the petals, and are of a deeper colour. The flowers are succeeded by conical capsules of a purplish red colour, having three cells, filled with small seeds. It flowers in May, June, and July, and the seeds ripen in autumn. This is now propagated in the nurseries as a flowering shrub, and may be treated in the same way as the third and fourth sorts.

The seventh sort was first brought to England from Constantinople, but has long been very common in the English gardens, for the roots spread and increase very fast, where it is permitted to stand long unremoved. The stalks of this are slender, and incline downward; they are garnished with oval, spear-shaped, smooth leaves, placed by pairs, sitting close to the stalks. The flowers are produced at the end of the stalks; these are very large, and of a bright yellow colour, with a great number of stamina, which stand out beyond the petals; there are five styles in each flower, which are of the same length with the stamina. The flowers are succeeded by pyramidal seed-vessels with five cells, containing many small seeds. It flowers in June and July.

This plant is easily propagated by parting of the root; the best time for this is in October, that the plants may be well established before the drought of spring, otherwise they will not produce many flowers. As this will grow under trees, so it is a very proper plant to place under shrubs and trees to cover the ground, where they will make a good appearance during the season of their flowering.

The

H Y P

The eighth sort grows naturally in the island of Minorca, from whence the seeds were sent to England, by Mr. Salvador, an apothecary at Barcelona, in the year 1718; this rises with a slender shrubby stalk in this country about two feet high, but in its native soil rises seven or eight feet high, sending out several weak branches of a reddish colour, which are marked where the leaves have fallen off with a cicatrice. The leaves are small, oval, and waved on their edges, having several small protuberances on their under side, sitting close to the stalks, half embracing them with their base. The flowers are produced at the top of the stalks; they are large, of a bright yellow colour, with a great number of stamina, which are a little shorter than the petals; these flowers have five styles, and are succeeded by pyramidal capsules with five cells, which have a strong smell of turpentine, and are filled with small brown seeds: this plant has a succession of flowers great part of the year, which renders it valuable; it is too tender to live through the winter in the open air in England, but requires no artificial heat: if the plants are placed in a dry airy glass-case in winter, where they may be protected from frost, and enjoy a good share of fresh air in mild weather, they will thrive better than in a warmer situation; but they must by no means be placed in a damp air, for their shoots soon grow mouldy and decay with damp, nor should the plants have much water during the winter; but in summer they should be exposed in the open air, and in warm weather they should be gently watered three times a week; they should have a loose sandy soil, not over rich. This is propagated by cuttings, which should be planted in June, in pots filled with light earth, and plunged into a very moderate hot-bed, whose heat is declining, shading them from the sun in the heat of the day, and now and then refreshing them with water; these cuttings, so managed, will put out roots in six or seven weeks, when they should be carefully taken up, and each planted into a separate small pot, placing them in the shade till they have taken new root; then they may be removed to a sheltered situation, where they may remain till the frost comes, when they should be removed into shelter.

If these are propagated by seeds, they should be sown in autumn, in the same way as is before directed for the fifth sort, and the plants treated in the same manner as those raised from cuttings.

The ninth sort is the common Tutsan, or Park-leaves, which is sometimes used in medicine. It grows naturally in woods in several parts of England, so is not often admitted into gardens; this hath a shrubby stalk, which rises two feet high, sending out some small branches toward the top; these, and also the stalks, are garnished with oval heart-shaped leaves, sitting close to them with their base, they are placed by pairs at every joint. The flowers are produced in small clusters at the end of the stalk; these are yellow, but smaller than either of the sorts here mentioned; they have many long stamina, which stand out beyond the flower, and three styles. The germen afterward turns to a roundish fruit, covered with a moist pulp, which, when ripe, is black. The capsule has three cells, containing small seeds. It flowers in June, and the seeds are ripe in autumn. It hath a perennial root, and may be propagated by parting it in autumn; it loves shade and a strong soil.

The tenth sort grows naturally in North America; this rises with an upright herbaceous stalk three feet and a half high, sending out several small branches upward, which come out opposite, and are garnished with oblong leaves placed opposite, which half embrace the stalk with their base. At the end of each stalk is produced one pretty large yellow flower, with an obtuse empalement, having many stamina, which are equal in length with the petals, and five styles which are so closely joined as to appear but one. The stigmas are reflexed, which denote their number. This sort seldom ripens seeds here, so is propagated by

H Y S

parting the roots. The best time for this is in autumn; it should have a light soil and an open situation. The flowers appear the latter end of July, and in August.

The eleventh sort grows naturally in China, from whence the seeds were brought to the Right Hon. the Earl of Northumberland, and the plants were raised in his Lordship's curious garden at Stanwick; and by his Lordship's generosity the Chelsea garden was furnished with this plant.

The root of this plant is composed of many ligneous fibres, which strike deep in the ground; from which arise several shrubby stalks near two feet high, covered with a purplish bark, and garnished with stiff smooth leaves about two inches long, and a quarter of an inch broad, placed by pairs, sitting close to the stalk; they are of a lucid green on their upper side, and gray on their under, having many transverse veins running from the midrib to the border. The flowers are produced at the top of the stalks, growing in small clusters, each standing upon a short distinct foot-stalk; these have an empalement of one leaf, divided into five obtuse segments almost to the bottom, which is of a deep purple colour. The flower is composed of five large obtuse petals, of a bright yellow colour; these are concave, and in the center is situated an oval germen supporting a single style, crowned by five slender stigmas, which bend on one side; the style is attended by a great number of stamina which are longer than the petals, and terminated by roundish summits.

This plant continues in flower great part of the year, which renders it the more valuable; and if it is planted in a very warm situation, it will live in the open air; but those plants which stand abroad will not flower in winter, as those do which are removed into shelter in autumn.

It may be propagated by slips from the root, or by laying down of the branches; if by slips, they should be planted in the spring on a moderate hot-bed, which will forward their putting out new roots; the layers should also be laid down at the same time, which will have taken root by autumn, when they may be transplanted into pots, and sheltered under a frame in winter; and in the spring, part of these may be planted in a warm border, and the others continued in pots to be screened in winter, lest those in the open air should be killed.

HYPERICUM FRUTEX. See SPIRÆA.

HYPOCHÆRIS, a sort of Hawkweed, of which there are two or three species, which grow naturally in England; the others are seldom admitted into gardens, therefore I shall not enumerate them.

HYPOPHYLLOSPERMOUS PLANTS [of ὑπό, under, φύλλον, a leaf, and σπέρμα, seed,] are such plants as bear their seeds on the backsides of their leaves.

HYSSOPUS. Tourn. Inst. R. H. 200, tab. 95. Lin. Gen. Plant. 628. [takes its name from the Hebrew word חִסּוֹן, in which language Hyssop signifies a holy herb, or for purging or cleansing sacred places, as it is said in the Psalms, Purge me with Hyssop. But what plant the Hyssop of the antients was, is not known, but that it seems to have been a low plant, because Solomon is said to have described the plants from the Cedar to the Hyssop.] Hyssop; in French, *Hisope*.

The CHARACTERS are,

The empalement of the flower is oblong, cylindrical, streaked, and permanent. It is of one leaf, cut into five acute parts at the top. The flower is of one petal, of the grinning kind, with a narrow cylindrical tube the length of the empalement. The chaps are inclining. The upper lip is short, plain, roundish, erect, and indented at the top. The under lip is trifid, the two side segments being shorter than the middle one, which is crenated. It hath four stamina, which stand apart; two of them are longer than the petal, the other two are shorter, terminated by single summits. It hath four germen, with a single style situated

situated under the upper lip, crowned by a bifid stigma. The germen afterward becomes so many oval seeds sitting in the empalement.

This genus of plants is ranged in the first section of Linnæus's fourteenth class, intitled *Didynamia Gymnospermia*, which contains those plants whose flowers have two long and two short stamina, and are succeeded by naked seeds in the empalement.

The SPECIES are,

1. *HYSSOPUS (Officinalis) spicis fecundis.* Hort. Cliff. 304. *Hyssop with fruitful spikes.* *Hyssopus officinarum cœrulea seu spicata.* C. B. P. 217. *Hyssop of the shops with blue spikes, or the common Hyssop.*
2. *HYSSOPUS (Rubra) spicis brevioribus, verticillis compactis.* *Hyssop with shorter spikes, and whorls more compact.* *Hyssopus rubro flore.* C. B. P. 217. *Hyssop with a red flower.*
3. *HYSSOPUS (Altissimis) spicis longissimis verticillis distantibus.* *Hyssop with the longest spikes, and whorls at a greater distance.* *Hyssopus verticillis florum rarioribus.* Houtt. *Hyssop with the whorls of flowers thinly ranged.*
4. *HYSSOPUS (Nepetoides) caule acuto quadrangulo.* Hort. Upsal. 163. *Hyssop with an acute square stalk.* *Sideritis Canadensis altissima, scrophulariæ folio, flore flavescente.* Tourn. Inst. 192. *Tallest Canada Ironwort, with a Figwort leaf and a yellowish flower.*
5. *HYSSOPUS (Lophanthus) corollis subresupinatis staminibus corollâ brevioribus.* Hort. Upsal. 162. *Hyssop with transverse petals, and the lower stamina shorter than the petal.* *Nepeta floribus obliquis.* Dill. *Catmint with oblique flowers.*

The first sort, which is the only one cultivated for use, grows a foot and a half high. The stalks are first square, but afterward become round; their lower parts are garnished with small spear-shaped leaves placed opposite, without foot-stalks, and seven or eight very narrow erect leaves (or bractæa) rising from the same joint. The upper part of the stalk is garnished with whorls of flowers, the lower ones standing half an inch apart, but the upper are almost joined together. The upper lip of the flower is indented at the top, and the under is cut into three parts, the middle being deeply indented at the point. There are four stamina in each flower, which spread at a distance from each other; the two upper are the shortest, which are situated on each side the upper lip; the two longer stand close to the two side segments, and are terminated by twin summits. At the bottom of the tube are situated four naked germen, supporting a slender style, sitting close to the upper lip, crowned by a bifid stigma; these germen afterward become four oblong black seeds, sitting in the empalement. The whole plant has a strong aromatic scent. It flowers in July and August, and the seeds ripen in September, but the roots will abide many years; it grows naturally in the Levant. There is a variety of this with white flowers, but doth not differ from the blue in any other particular.

The second sort doth not grow so tall as the first; the stalks branch more, and the spikes of flowers are much shorter than those of the first. The whorls are closer together, and have long narrow leaves situated under each. The flowers are of a fine red colour, and appear at the same time with the former. This sort is not quite so hardy as the common, for in 1739 the plants were all destroyed by the cold; this is certainly a distinct species, for I cultivated it from seeds twenty years, and never observed it to vary.

The third sort grows much taller than either of the other. The leaves are narrower, the whorls of flowers are farther asunder, the spikes of flowers are much longer, the flowers are larger, and of a deeper blue than those of the common sort, and the plant hath not so strong an odour. It flowers at the same time as the first.

These three sorts of Hyssop are propagated either by seeds or cuttings; if by the seeds, they must be sown in March, upon a bed of light sandy soil; and when the plants come up, they should be transplanted out

to the places where they are to remain, placing them at least a foot asunder each way; but if they are designed to abide in those places for a long time, two feet distance will be small enough, for they grow pretty large, especially if they are not frequently cut, to keep them within compass; they thrive best upon a poor dry soil, in which situation they will endure the cold of our climate better than when they are planted on a richer soil. If you would propagate them by cuttings, they should be planted in April or May, in a border where they may be defended from the violent heat of the sun; and being frequently watered, they will take root in about two months; after which, they may be transplanted where they are to continue, managing them as was before directed for the seedling plants.

The first sort was formerly more cultivated than at present in England, that being the sort commonly used in medicine. The other species are preserved in curious gardens for their variety, but they are seldom cultivated for use.

They are very hardy plants, which will endure the cold of our winters in the open air, provided they are planted in a dry undunged soil; for when they are planted in a rich soil, they grow very luxuriant in summer, and are less able to resist the cold in winter; so that when any of these plants grow out of the joints of old walls, (as they frequently do) they will resist the most severe frost, and will be much more aromatic than those which grow in a rich soil.

The fourth sort grows naturally in North America; this hath a perennial root and an annual stalk, which decays in autumn. It rises with an upright square stalk near four feet high, garnished with oblique heart-shaped leaves, which are sawed on their edges, and end in acute points; they are placed opposite on short foot-stalks. The flowers grow in close thick spikes four or five inches long, at the top of the stalks. The upper lip is divided into two roundish segments, the lower one is divided into three, the two side segments standing erect, and the middle one is reflexed, and acutely sawed at the end. The two upper stamina, which are situated on each side the upper lip are the longest, the other two shorter join the two side segments of the lower lip; they are terminated by small summits. The germen are situated at the bottom of the tube, having a slender style under the upper lip, crowned by a bifid stigma. The germen afterward becomes four oblong brown seeds, sitting in the tubulous empalement. This sort flowers in July, and the seeds ripen in September.

There is a variety of this sort with purple stalks and purplish flowers. The leaves stand upon longer foot-stalks, and the spikes of flowers are thicker, but I cannot say if it is a distinct species or only a variety. It grows naturally in the same country with the other. It is titled, *Betonica maxima, folio scrophulariæ, floribus incarnatis*, by Herman. Par. Bat. 106.

The fifth sort grows naturally in Siberia. The seeds of this were sent me from the Imperial garden at Peterburgh, by the title of *Lophanthus*, and afterward I received some from Holland, which were titled, *Nepeta floribus obliquis.* Dill. This is a perennial plant with a strong fibrous root, sending out many square stalks, which divide into smaller branches, garnished with oblong leaves, crenated on their edges, set on by pairs. The flowers are produced at each joint in small clusters, two foot-stalks arising from the base of the leaves, about half an inch long, both inclining to one side of the stalk; each of these foot-stalks divide again into two smaller, and these do each support a cluster of four or five flowers, which have swelling tubulous empalements, cut into five acute segments at the top. The tube of the petal is longer than the empalement. The lips of the flower are oblique to it, being situated horizontally. The two upper stamina and the style stand out beyond the petal, but the other are shorter. The flowers are blue, and appear in June and July, and the seeds ripen in September.

Both

H Y S

Both these sorts are very hardy, and may be easily propagated by seeds, which should be sown in autumn; for those sown in the spring, often lie a year in the ground before they vegetate; when the plants come up, they must be kept clean from weeds, and thinned where they are too close. The following autumn they should be transplanted where they are to remain, and the plants will flower in summer, and produce seeds, but the roots will abide some years.

H Y S

It hath been a great dispute amongst modern writers, whether the Hyssop now commonly known is the same which is mentioned in scripture; about which there is great room to doubt, there being very little grounds to ascertain that plant, though it is most generally thought to be the Winter Savory, which plant is now in great request amongst the inhabitants of the eastern countries, for outward washings or purification.

JACEA. See CENTAUREA.

JACOBÆA. See SENEIO and OTHONNA.

JACQUINIA. Lin. Gen. 254.

The CHARACTERS are,

The empalement of the flower is composed of five roundish concave leaves, and is permanent. The flower has one bell-shaped petal, which is bellied, cut into ten segments. It hath five awl-shaped stamina arising from the receptacle, terminated by balbert-shaped summits, and an oval germen supporting a style the length of the stamina, crowned by a beaded stigma. The germen afterward becomes a roundish berry with one cell, containing one seed.

This genus of plants is ranged in the first section of Linnæus's fifth class, intituled Pentandria Monogynia, the flowers having five stamina and one style.

The SPECIES are,

1. **JACQUINIA** (*Ruscifolia*) foliis lanceolatis acuminatis. Jacq. Amer. 15. Lin. Sp. 271. *Jacquinia with spear-shaped acute-pointed leaves.* Fruticulus foliis rusci stellatis. Hort. Elth.
2. **JACQUINIA** (*Armilaris*) foliis obtusis cum acumine. Jacq. Amer. 15. Lin. Sp. 272. *Jacquinia with blunt leaves ending in acute points.* Chrysophyllum Barbasco. Læfl. it. 204.
3. **JACQUINIA** (*Linearis*) foliis linearibus acuminatis. Jacq. Amer. 15. Lin. Sp. 272. *Jacquinia with linear sharp-pointed leaves.*

The first sort grows naturally in the island of Cuba, and in some other warm parts of America; it rises with a shrubby stalk about a foot high, which is ligneous at the bottom, and about the size of a swan's quill, covered with a dark brown bark, sending out a few slender branches, garnished at intervals with hand-shaped stiff leaves, placed in whorls round them; these are stiff like those of Butcher's Broom, ending with sharp points, of a deep green on their upper side, but pale on their under; the flowers are (according to Plumier's figure) produced from between the leaves on the top of the branches; but having seen no flowers in England, so I can give no farther account of them.

The second sort grows naturally at Carthagera, Martinico, and other parts of South America, where it rises with a shrubby stalk four or five feet high, dividing toward the top into four branches, which are situated in whorls round the principal stalk, garnished with oblong blunt leaves, placed also in whorls, having a short slender apex. The flowers are produced in a racemus on the end of the branches, each containing five or six white flowers of a thick consistence, which

J A S

have a scent like Jasmine flowers, which they retain after they decay, so are worn by the ladies of those countries for ornament.

The third sort grows naturally on the borders of the sea, in the island of Dominica; this is an under-shrub, of a very low growth, rarely rising about two feet high, dividing into several branches, garnished with linear stiff leaves, ending with a thorn; these are placed in whorls round the branches, and from the middle of the whorls come out the foot-stalks of the flowers, each being terminated by one small white flower without scent.

As these plants are natives of hot countries, so they will not live in England, unless they are placed in a warm stove, and treated in the manner directed for other plants from the same countries, giving them little water in winter, and in warm weather plenty of fresh air. They are raised from seeds, when they can be procured from the countries where they naturally grow; which must be sown on a hot-bed, and may afterward be propagated by cuttings, though it is with difficulty they take root.

JALAPA. See MIRABILIS.

JASIONE. Lin. Gen. Plant. 896. This is the Ranunculus scabiosæ capitulo cœruleo. C. B. P. 22. Rampions with Scabious heads. This plant grows naturally on sterile ground in most parts of England, and is rarely admitted into gardens.

JASMINOIDES. See CESTRUM and LYCIUM.

JASMINUM. Tourn. Inst. R. H. 597. tab. 368. Lin. Gen. Plant. 17. [This name is Arabic.] The Jasmine, or Jessamine-tree; in French, *Jasmin*.

The CHARACTERS are,

The flower hath a tubulous empalement of one leaf, which is permanent, and cut into five segments at the brim, which are erect. The flower is of one petal, having a long cylindrical tube, cut into five segments at the top, which spread open. It hath two short stamina, which are terminated by small summits, and are situated within the tube of the petal. In the center is situated a roundish germen, supporting a slender style, crowned by a bifid stigma. The germen afterward turns to an oval berry, with a soft skin inclosing two seeds, which are flat on those sides which join, and convex on the other.

This genus of plants is ranged in the first section of Linnæus's second class, intituled Diandria Monogynia, in which he ranges those plants whose flowers have two stamina and one style.

The SPECIES are,

1. **JASMINUM** (*Officinale*) foliis oppositis pinnatis, foliolis acuminatis. *Jasmine with winged leaves placed opposite,*

posite, whose lobes end in acute points. Jasminum vulgatum, flore albo. C. B. P. 397. The common white Jasmine.

2. JASMINUM (*Humile*) foliis alternis ternatis simplicibusque, ramis angulatis. Hort. Upsal. 5. *Jasmine with trifoliate winged leaves placed alternate, and angular branches. Jasminum humile luteum. C. B. P. 397. Dwarf yellow Jasmine, commonly called the Italian yellow Jasmine.*
3. JASMINUM (*Fruticans*) foliis alternis ternatis simplicibusque, ramis angulatis. Hort. Cliff. 5. *Jasmine with trifoliate single leaves placed alternate, and angular branches. Jasminum luteum, vulgò dictum bacciferum. C. B. P. 398. The common yellow Jasmine.*
4. JASMINUM (*Grandiflorum*) foliis oppositis pinnatis, foliolis brevioribus obtusis. *Jasmine with winged leaves placed opposite, whose lobes are shorter and obtuse. Jasminum humilis, magno flore. C. B. P. 398. The Spanish white, or Catalonian Jasmine with a larger flower.*
5. JASMINUM (*Odoratissimum*) foliis alternis ternatis, foliolis ovatis, ramis teretibus. *Jasmine with trifoliate leaves placed alternate, whose lobes are oval, and taper branches. Jasminum Indicum flavum odoratissimum. Fer. Flor. The sweet-scented yellow Indian Jasmine.*
6. JASMINUM (*Azoricum*) foliis oppositis ternatis, foliolis cordato-acuminatis. *Jasmine with trifoliate leaves placed opposite, whose lobes are heart-shaped and pointed. Jasminum Azoricum trifoliatum, flore albo, odoratissimum. Hort. Amst. The three-leaved Azorian Jasmine, with very sweet white flowers, commonly called the Ivy-leaved Jasmine.*
7. JASMINUM (*Capense*) foliis lanceolatis oppositis integerrimis, floribus triandris. *Jasmine with spear-shaped entire leaves placed opposite, and flowers with three stamina.*

The first sort is the common white Jasmine, which is a plant so generally known as to need no description. This grows naturally at Malabar, and in several parts of India, yet has been long inured to our climate, so as to thrive and flower extremely well, but never produces any fruit in England; this hath weak trailing branches, so requires the assistance of a wall or pale to support them. It is easily propagated by laying down the branches, which will take root in one year, and may then be cut from the old plant, and planted where they are designed to remain: it may also be propagated by cuttings, which should be planted early in the autumn, and if the winter should prove severe, the surface of the ground between them should be covered with tan, sea-coal ashes, or saw-dust, which will prevent the frost from penetrating deep into the ground, and thereby preserve the cuttings; or where these are wanting, some Peas-haulm, or other light covering should be laid over the cuttings in hard frost; but these must be removed when the weather is mild, for they will keep off the air and occasion damps, which often destroy them.

When these plants are removed, they should be planted where they are designed to be continued, which should be either against some wall, pale, or other fence, where the flexible branches may be supported; for although it is sometimes planted as a standard, and formed into a head, yet it will be very difficult to keep it in any handsome order; or if you do, you must cut off all the flowering branches; for the flowers are always produced at the extremity of the same year's shoots, which, if shortened before the flowers are blown, will entirely deprive the trees of flowers. These plants should be permitted to grow rude in the summer, for the reason before given; nor should you prune and nail them until the middle or latter end of March, when the frosty weather is past; for if it should prove sharp frosty weather after their rude branches are pruned off, and the strong ones are exposed thereto, they are very often destroyed; and this plant being very backward in shooting, there will be no danger of hurting them by late pruning.

There are two varieties of this with variegated leaves, one with white, and the other yellow stripes, but the

latter is the most common: these are propagated by budding them on the plain Jasmine, and it often happens, that the buds do not take, but yet they have communicated their gilded miasma to the plants; so that in a short time after, many of the branches both above and below the places where the buds have been inserted have been thoroughly tinged; and the following year I have often found very distant branches, which had no other communication with those which were budded than by the root, have been as compleatly tinged as any of the nearer branches, so that the juices must have descended into the root. The two striped sorts should be planted in a warm situation, especially the white striped; for they are much more tender than the plain, and are very subject to be destroyed by great frosts, if they are exposed thereto; therefore the white striped should be planted to a south or south-west aspect, and in very severe winters their branches should be covered with mats or straw, to prevent their being killed: the yellow striped is not so tender, so may be planted against walls to east or west aspects; but these plants with variegated leaves, are not so much in esteem as formerly.

The second sort is frequently called Italian yellow Jasmine by the gardeners, the plants being annually brought from thence by those who come over with Orange-trees. These plants are generally grafted upon the common yellow Jasmine stocks, so that if the graft decays, the plants are of no value. This sort is somewhat tenderer than the common, yet it will endure the cold of our ordinary winters, if it is planted in a warm situation. The flowers of this kind are generally larger than those of the common yellow sort, but have very little scent, and are seldom produced so early in the season. It may be propagated by laying down the tender branches, as was directed for the common white sort; or by budding or inarching it upon the common yellow Jasmine, the latter of which is preferable, as making the plants hardier than those which are obtained from layers: they should be planted against a warm wall, and in very severe winters will require to be sheltered with mats, or some other covering, otherwise they are subject to be destroyed. The manner of dressing and pruning being the same as was directed for the white Jasmine, I shall not repeat it.

The third sort was formerly more cultivated in the gardens than at present, for as the flowers have no scent, so few persons regard them. This hath weak angular branches which require support, and will rise to the height of eight or ten feet, if planted against a wall or pale; but the plants do often produce a great number of suckers from their roots, whereby they become troublesome in the borders of the pleasure-garden; and as they cannot be kept in any order as standards, so there are few of the plants at present introduced into gardens. It is easily propagated by suckers or layers.

The fourth sort grows naturally in India, and also in the island of Tobago, where the woods are full of it; the late Mr. Robert Millar sent me over a great quantity of it from thence. This hath much stronger branches than the common white sort; the leaves are winged, and are composed of three pair of short obtuse lobes, terminated by an odd one, ending in an acute point; these lobes are placed closer than those of the common Jasmine, and are of a lighter green; the flowers come out from the wings of the stalks, standing on foot-stalks which are two inches long, each sustaining three or four flowers, which are of a bluish red on their outside, but white within; the tube of the flower is longer, the segments are obtuse, twisted at the mouth of the tube, and are of a much thicker texture than those of the common sort, so that there is no doubt of its being a distinct species: the reason for Dr. Linnæus's supposing it to be so, was by mistake; for as these plants are generally grafted upon stocks of the common Jasmine, so there are always shoots coming out from the stocks of that sort, which,

if permitted to stand, will produce flowers; and these often starve and kill the grafts, so that there will be only the common sort left; and this has been the case with some plants which he examined, therefore supposed the difference of the other sort was wholly owing to culture; whereas, if he had only observed the difference of their leaves, he would have certainly made two distinct species of them; which he has now done in the last edition of his species.

This plant is propagated by budding or inarching it upon the common white Jasmine, on which it takes very well, and is rendered hardier than those which are upon their own stocks. But the plants of this kind being brought over from Italy every spring in so great plenty, they are seldom raised here: I shall therefore proceed to the management of such plants as are usually brought into England from the place above-mentioned, which are generally tied up in small bunches, containing four plants, and their roots wrapped about with moss, to preserve them from drying; which, if it happen that the ship has a long passage, will often occasion them to push out strong shoots from their roots, which must always be taken off before they are planted, otherwise they will exhaust the whole nourishment of the plant, and destroy the graft.

In the making choice of these plants, you should carefully observe if their grafts are alive, and in good health: for if they are brown and shrunk, they will not push out, so that there will be only the stock left, which is of the common sort.

When you receive these plants, you must clear the roots of the moss, and all decayed branches should be taken off; then place their roots into a pot or tub of water, which should be set in the green-house, or some other room, where it may be screened from the cold; in this situation they may continue two days, after which you must prune off all the dry roots, and cut down the branches within four inches of the place where they were grafted, and plant them into pots filled with fresh light earth; then plunge the pots into a moderate hot-bed of tanners bark, observing to water and shade them; as the heat of the season may require. In about a month or six weeks after they will begin to shoot, when you must carefully rub off all such as are produced from the stock below the graft; and you must now let them have a great share of air, by raising the glasses in the heat of the day; and as the shoots extend, they should be topped, to strengthen them, and by degrees should be hardened to endure the open air, into which they should be removed the beginning of June, but must have a warm situation the first summer; for if they are too much exposed to the winds, they will make but indifferent progress, being rendered somewhat tender by the hot-bed. If the summer proves warm, and the trees have succeeded well, they will produce some flowers in the autumn following, though they will be few in number, and not near so strong as they will be the succeeding years, when the trees are stronger and have better roots.

These plants are commonly preserved in green-houses, with Oranges, Myrtles, &c. and during the winter season, will require to be frequently watered; which should be performed sparingly each time, especially in cold weather, for too much wet at that season will be apt to rot the fibres of their roots; they should also have a great share of fresh air when the weather, will permit, for which purpose they should be placed in the coolest part of the green-house, among plants that are hardy, where the windows may be opened every day, except in frosty weather; nor should they be crowded too close among other plants, which often occasions the tender part of their shoots to grow mouldy and decay. In April the shoots of these plants should be shortened down to four eyes, and all the weak branches should be cut off; and if you have the conveniency of a glass-stove, or a deep frame, to place the pots in at that season, to draw them out again, it will be of great service in forwarding their flowering; yet still you should be careful

not to force them too much; and as soon as they have made shoots three or four inches long, the glasses should be opened in the day time, that the plants may, by degrees, be inured to the open air, into which they should be removed by the latter end of May, or the beginning of June; otherwise their flowers will not be so fair, nor continue so long. If the autumn prove favourable, these plants will continue to produce fresh flowers until November; and sometimes when they are strong, they will continue flowering later; but then they must have a great share of air when the weather is mild and will admit of it, otherwise the flower-buds will grow mouldy and decay. But notwithstanding most people preserve these plants in green-houses, yet they will endure the cold of our ordinary winters in the open air, if planted against a warm wall, and covered with mats in frosty weather; they will also produce ten times as many flowers in one season as those kept in pots, and the flowers will likewise be much larger; but they should not be planted abroad till they have acquired strength, so that it will be necessary to keep them in pots three or four years, whereby they may be sheltered from the frost in winter; and when they are planted against the wall, which should be in May, that they may take good root in the ground before the succeeding winter, you must turn them out of the pots, preserving the earth to their roots; and having made holes in the border where they are to be planted, you should place them therein, with their stems close to the wall; then fill up the holes round their roots with good, fresh, rich earth, and give them some water to settle the ground about them, and nail up their shoots to the wall, shortening such of them as are very long, that they may push out new shoots below to furnish the wall, continuing to nail up all the shoots as they are produced. In the middle, or toward the latter end of July, they will begin to flower, and continue to produce new flowers until the frost prevents them; which, when you observe, you should carefully cut off all the tops of such shoots as have buds formed upon them, as also those which have the remains of faded flowers left; for if these are suffered to remain on, they will soon grow mouldy, especially when the trees are covered, and thereby infect many of the tender branches, which will greatly injure the trees.

Toward the middle of November, if the weather proves cold and the nights frosty, you must begin to cover your trees with mats, which should be nailed over them pretty close; but this should be done when the trees are perfectly dry, otherwise the wet being lodged upon the branches, will often cause a mouldiness upon them, and the air being excluded therefrom, will rot them in a short time: it will also be very necessary to take off the mats as soon as the weather will permit, to prevent this mouldiness, and only keep them close covered in frosty weather, and in the nights; at which time you should also lay some mulch upon the surface of the ground about their roots, and fasten some bands of hay about their stems, to guard them from the frost; and in very severe weather, you should add a double or treble covering of mats over the trees; by which method, carefully performed, you may preserve them through the hardest winters. In the spring, as the weather is warmer, you should by degrees take off the covering; but you should be careful not to expose them too soon to the open air, as also to guard them against the morning frosts and dry easterly winds, which often reign in March, to the no small destruction of tender plants if they are exposed thereto; nor should you quite remove your covering until the middle of April, when the season is settled; at which time you should prune the trees, cutting out all decayed and weak branches, shortening the strong ones to about two feet long, which will cause them to shoot strong, and produce many flowers.

There is a variety of this with semi-double flowers, which is at present more rare in England, and only to be found in some curious gardens; though in Italy it is pretty common, from whence it is sometimes

brought over amongst the single; the flowers of this kind have only two rows of leaves, so that it is rather cultivated for its curiosity, than for any extraordinary beauty in the flowers. This may be propagated by budding it upon the common white Jasmine, as hath been directed for the single, and must be treated in the same manner.

The fifth sort grows naturally in India; this rises with an upright woody stalk eight or ten feet high, covered with a brown bark, sending out several branches which want no support; these are closely garnished with trifoliate leaves of a lucid green, which are placed alternate on the branches; the two side lobes of these leaves which grow opposite, are much less than the end one; they are oval and entire, continuing green all the year: the flowers are produced at the end of the shoots in bunches, which have long slender tubes, and are divided at the top into five obtuse segments which spread open; these flowers are of a bright yellow, and have a most grateful odour. They come out in July, August, September, and October, and sometimes continue to the end of November; they are frequently succeeded by oblong oval berries, which turn black when ripe, and have each two seeds.

This sort of Jasmine is propagated either by seeds, or laying down the tender branches; if you would propagate them by seeds, which they sometimes produce in England, you should make a moderate hot-bed in the spring, into which you should plunge some small pots, filled with fresh light earth; and in a day or two after, when you find the earth in the pots warm, you must put your seeds therein; about four in each pot will be sufficient, covering them about an inch thick with the same light earth, and observe to refresh the pots with water as often as you shall perceive the earth dry; but do not give them too much at each time, which would be apt to rot the seeds.

In about six or eight weeks after sowing, the plants will appear above ground, at which time it will be necessary to remove the pots into another fresh hot-bed, of a moderate temperature, in order to bring the plants forward; you must also be careful to water them as often as is necessary, and in the great heat of the day the glasses should be tilted pretty high, and shaded with mats, to prevent the plants from being scorched with heat. About the middle of May you should begin to harden them to the open air, by taking off the glasses when the weather is warm; but this must be done cautiously, for you should not expose them to the open sun in a very hot day at first, which would greatly injure them; but rather take off the glasses in warm cloudy weather at first, or in gentle showers of rain, and so by degrees inure them to bear the sun; and in June you should take the pots out of the hot-bed, and carry them to some well sheltered situation, where they may remain until the beginning of October; at which time they must be carried into the green-house, observing to place them where they may enjoy as much free air as possible when the windows are opened, as also to be clear from the branches of other plants.

During the winter season they will require to be often watered, but you must be careful not to give them too much at each time; and in March you must remove these plants each into a separate pot, being careful not to take the earth from their roots; and if at this time you plunge them into a fresh moderate hot-bed, it will greatly facilitate their rooting again, and be of great service to the plants; but when they are rooted, you must give them a great deal of air; for if you draw them too much, they will become weak in their stems, and incapable to support their heads, which is a great defect in these trees.

You must also harden them to the open air, into which they should be removed about the middle of May, observing, as was before directed, to place them in a situation that is defended from strong winds, which are injurious to these plants, especially while they are young. In winter house them as before, and

continue the same care, with which they will thrive very fast, and produce annually great quantities of flowers.

These plants are pretty hardy, and will require no other care in winter, than only to defend them from hard frosts; nor do I know whether they would not live in the open air, if planted against a warm wall, which is what should be tried by planting some against a wall for that purpose; and I think we have little reason to doubt of the success, since they are much hardier than the Spanish; but there is this difference between them, viz. these plants have large, thick, Evergreen leaves, so that if they were covered with mats, as was directed for the Spanish Jasmine, the leaves would rot and decay the shoots; but as these will only require to be covered in extreme frost, so if their roots are well mulched, and a mat or two loosely hung over them in ordinary frosts, it will be sufficient; and these mats being either rolled up, or taken quite off in the day, there will be no great danger of their being hurt, which only can proceed from being too long close covered.

In the spring these should be pruned, when you should cut off all decayed branches; but you must not shorten any of the other branches, as was directed for the Spanish sort, for the flowers of this kind are produced only at the extremity of the branches, which, if shortened, they would be cut off; and these growing of a more ligneous substance than the other, will not produce shoots strong enough to flower the same year. If you would propagate this plant from layers, the shoots should be laid down in March; and if you give them a little cut at the joint, as is practised in laying of Carnations, it will promote their rooting: you should always observe to refresh them often with water, when the weather is dry; which, if carefully attended to, the plants will be rooted by the succeeding spring, fit to be transplanted, when they must be planted in pots filled with light earth, and managed as was before directed for the seedling plants.

This sort is frequently propagated, by inarching the young shoots into stocks of the common yellow Jasmine, but the plants so raised do not grow so strong as those which are upon their own stock; besides, the common yellow Jasmine is very apt to send out a great number of suckers from the root, which renders the plants unsightly; and if these suckers are not constantly taken off as they are produced, they will rob the plants of their nourishment.

The sixth sort grows naturally in the Azores; this hath long slender branches which require support, and may be trained twenty feet high; they are garnished with trifoliate leaves, whose lobes are large and heart-shaped, of a lucid green, and are placed opposite on the branches; they continue all the year. The flowers are produced at the end of the branches, in loose bunches; they have long narrow tubes, which at the top are cut into five segments spreading open; they are of a clear white, and have a very agreeable scent. This flowers at the same time with the former; the gardeners call it frequently the Ivy-leaved Jasmine.

The Azorian Jasmine is also pretty hardy, and requires no more shelter than only from hard frosts; and I am apt to think, if this sort was planted against a warm wall, and managed as hath been directed for the yellow Indian Jasmine, it would succeed very well; for I remember to have seen some plants of this kind growing against a wall in the gardens at Hampton Court, where they had endured the winter, and were in a more flourishing state than ever I saw any of the kind in pots, and produced a greater quantity of flowers. These plants are propagated in the same manner as the yellow Indian, and require the same management.

These plants are as deserving of a place in all green-houses, as any which are there preserved; for their leaves being of a shining green, make a good appearance all the year; and their flowers having a fine scent, and continuing so long in succession, renders them very valuable.

The seventh fort was brought from the Cape of Good Hope, by Captain Hutchinson of the Godolphin, who discovered it growing naturally, a few miles up the land from the sea, being drawn to it by the great fragrantcy of its flowers, which he smelt at some distance from the plant, which was then in full flower; and after having viewed the plant, and remarked the place of its growth, he returned thither the following day with proper help, and a tub to put it in, and caused it to be carefully taken up, and planted in the tub with some of the earth on the spot, and conveyed on board his ship, where it continued flowering great part of the voyage to England, where it arrived in good health, and has for some years continued flowering, in the curious garden of Richard Warner, Esq; at Woodford in Essex, who was so obliging as to favour me with branches of this curious plant in flower, to embellish one of the numbers of my figures of plants, where it is represented in the 180th plate.

This plant seems not to have been known to any of the botanists, for I have not met with any figure or description of it in any of the books; there is one fort which is figured in the Malabar garden, and also in Burman's plants of Ceylon, which approaches near this; it is titled *Nandi ervatum major*. Hort. Mal. But it differs from this, in having longer and narrower leaves; the tube of the flower is larger, and the segments do not spread so much as this; the flowers also of the Cape Jasmine fade to a buff colour before they decay, therefore there is no doubt of its being a different species from that of Dr. Burman; but it is surprizing that this plant should be unknown to the people at the Cape of Good Hope, for there was not one plant of it in their curious garden, nor could the captain see any other plant of it but that which he brought away.

The stem of this plant is large and woody, sending out many branches, which are first green, but afterward the bark becomes gray and smooth; the branches come out by pairs opposite, and have short joints; the leaves are also set opposite, close to the branches; they are five inches long, and two inches and a half broad in the middle, lessening to both ends, terminating in a point; they are of a lucid green, having several transverse veins from the midrib to the borders; they are entire, and of a thick consistence. The flowers are produced at the end of the branches, sitting close to the leaves; they have a tubulous empalement, with five corners or angles, cut deep at the brim, into five long narrow segments, ending in acute points: the flower hath but one petal, for although it is cut into many deep segments at the top, yet these are all joined in one tube below; some of these flowers are much more double than others, having three or four orders of petals; these which have so many, have only a bifid stigma, but those which are less double have trifid stigmas. All those flowers which I have examined have but one or two stamina, which may be occasioned by the fulness of the flowers; as is often observed in many kinds of plants, whose flowers have a greater number of petals than usual, many of which want both parts of generation, and some of them have no male parts. This flower, when fully blown, is as large as a middling Rose, and some of them are as double as the Damask Rose; they have a very agreeable odour; on the first approach it is something like that of the Orange flower, but when more closely smelt to, has the odour of the common double white Narcissus. The season of this plant flowering in England, is in July and August, but in its native country it is supposed to flower great part of the year; for Captain Hutchinson, who brought the plant over, said there was a succession of flowers on it, till the ship arrived in a cold climate, which put a stop to its growth.

Dr. Linnæus has been induced from what has been printed in the Transactions of the Royal Society, to alter the title of this plant to *Gardenia*; but as the description of the plant with its characters as there

printed, was taken from a double flower by some hasty people, who should have remembered what Linnæus has written to caution persons against regarding the double flowers of all kinds, in ranging them in their classes and genera, which if they had adhered to, they would not have made this mistake; for I have since raised several of the plants from seeds, some of which have produced flowers which were single, having all the marks of the double, the flowers altering to a buff colour before they faded; and all these flowers had each but three stamina and a trifid stigma; whereas in the characters set down by Linnæus, there is no stamina, but five linear antheræ, by which it is plain from the increase of the number of petals (or rather their segments) has occasioned an alteration in the parts of generation; which is also very conspicuous in the double flowers of *Dianthus*, where some flowers have but two or three stamina, when the same species with single flowers have usually ten. Linnæus also supposes the capsule of the seed to have two cells full of small seeds; but the persons who led him into this mistake, have since supposed the figure given by Dr. Plukenet in his 448th plate, under the title of *Um-ky*, to be the fruit of this plant; whereas this has three cells filled with angular sweet-scented seeds, as the specimens I have of that demonstrate, by which it is certain they are the fruit of a different plant; for the seeds which I sowed of this Jasmine, were a berry composed of two seeds like the other Jasmynes; therefore I have continued it under the same genus, with an addition to the title of its having three stamina.

This plant is easily propagated by cuttings during the summer season; the cuttings should be planted in pots, and plunged into a moderate hot-bed, covering them close with either bell or hand-glasses to exclude the external air, being careful to screen them from sun in the day time; when they have taken root they should be carefully parted, and put each into a separate small pot, plunging them again into the hot-bed, and shading them until they have taken new root, after which they should be gradually inured to the open air.

Though the cuttings of this plant take root freely, and make strong shoots a year or two after, yet in three or four years they are very apt to stint in their growth, their leaves turning pale and sickly, and frequently die soon after; this has happened every where within my knowledge, although the plants have been kept in various degrees of heat in winter; and in summer when they have been differently managed, they have frequently failed. I have also been informed by a gentleman who lived some years in India, where he had the plants in his garden, they frequently went off in the same manner. This has greatly lessened the value of the plants in England.

JATROPHA. Lin. Gen. Plant. 961. Manihot. Tourn. Inst. R. H. 958. tab. 438. Cassada, or Cassava; in French *Cassave*.

The CHARACTERS are,

It hath male and female flowers in the same plant; the male flowers have a scarce visible empalement; they are salver-shaped, of one petal, with a short tube, whose brim is cut into five roundish segments which spread open; they have ten awl-shaped stamina, five being alternately shorter than the other, and are joined close together, standing erect in the center of the flower, terminated by roundish loose summits. The female flowers which are situated in the same umbel have no empalement, but have five petals spread open like a Rose. In the center is a roundish germen with three deep furrows, supporting three styles, crowned by single stigmas. The germen afterward becomes a roundish capsule with three cells, each containing one seed.

This genus of plants is ranged in the ninth section of Linnæus's twenty-first class, intitled *Monœcia Monodelphia*,

nodephia, which includes those plants which have male and female flowers on the same plant, and the stamina are collected in one body.

The SPECIES are;

1. *JATROPHA* (*Manihot*) foliis palmatis, lobis lanceolatis integerrimis lævibus. Lin. Sp. Plant. 1007. *Jatropha* with hand-shaped leaves, whose lobes are spear-shaped, entire, and smooth. Manihot Theveti, juca & cassavi. J. B. 2. 794. *The Manihot of Thevet, and the Juca or Cassava of John Baubin.*
2. *JATROPHA* (*Quinquelobatus*) foliis quinquelobatis, lobis acuminatis, acutè dentatis lævibus, caule fruticoso. *Jatropha* with leaves composed of five smooth lobes ending in points, which are sharply indented on their edges, and a shrubby stalk. *Jussievia frutescens, non spinosa, foliis glabris & minus laciniatis.* Houst. MSS. *Shrubby Jussievia without spines, and smooth leaves less divided.*
3. *JATROPHA* (*Urens*) aculeata, foliis quinquelobatis acutè incis, caule herbaceo. *Prickly Jatropha, with leaves having five lobes which are sharply cut on their edges, and an herbaceous stalk.* *Jussievia herbacea, spinosissima, urens, foliis digitatis & laciniatis.* Houst. MSS. *The most prickly stinging and herbaceous Jussievia, with fingered leaves which are jagged.*
4. *JATROPHA* (*Herbacea*) aculeata, foliis trilobis, caule herbaceo. Lin. Sp. Plant. 1007. *Prickly Jatropha, with leaves having three lobes and an herbaceous stalk.* *Jussievia herbacea spinosissima, urens, foliis trilobatis minimè incis.* Houst. MSS. *Prickly stinging herbaceous Jussievia, with leaves having three lobes, which are very slightly indented.*
5. *JATROPHA* (*Vitifolius*) foliis palmatis dentatis aculeatis. Hort. Cliff. 445. *Jatropha* with hand-shaped, indented, prickly leaves. Manihot spinosissima, folio vitigineo. Plum. Cat. 20. *The most prickly Cassava with a Vine leaf.*
6. *JATROPHA* (*Aconitifolius*) foliis lobatis dentatis acuminatis, urentibus, caule arboreo. *Jatropha* with lobated leaves which are indented, acute-pointed, and stinging, and a tree-like stalk. *Jussievia arborea, minus spinosa, floribus albis umbellatis, foliis aconiti urentibus.* Houst. MSS. *Tree Jussievia which is less prickly, with white flowers growing in umbels, and stinging leaves like those of Wolfsbane.*
7. *JATROPHA* (*Multifida*) foliis multipartitis lævibus, stipulis setaceis multifidis. Hort. Cliff. 445. *Jatropha* with smooth leaves divided into many parts, and bristly stipules with many points. *Ricinoides arbor Americana, folio multifido.* 656. *Tree American Bastard Ricinus with a many pointed leaf, commonly called French Physic Nut in America.*
8. *JATROPHA* (*Curcas*) foliis cordatis angulatis. Hort. Cliff. 445. *Jatropha* with angular heart-shaped leaves. *Ricinoides Americana gossypii folio.* Tourn. Inst. 656. *American Bastard Ricinus with a Cotton leaf, commonly called Physic Nut in America.*
9. *JATROPHA* (*Staphysagrisolia*) foliis quinquepartitis, lobis ovatis integris, setis glandulosis ramosis. Flor. Leyd. Prod. 202. *Jatropha* with leaves divided into five parts, the lobes whereof are oval and entire, and branching bristles arising from the glands. *Ricinoides Americana staphysagrisæ folio.* Tourn. Inst. 656. *American Bastard Ricinus, with a Stavesacre leaf, commonly called Belly-ach Weed in America.*

The first sort here mentioned, is the common Cassava or Cassava, which is cultivated for food in the warm parts of America, where, after the juice is expressed out of the root (which has a poisonous quality) it is ground into a kind of flour, and made up in cakes or puddings, and is esteemed a wholesome food.

This rises with a shrubby stalk six or seven feet high, garnished with smooth leaves, standing upon long foot-stalks alternately; they are composed of seven lobes, which are joined at their base in one center, where they are narrow, but increase in their breadth till within an inch and a half of the top, where they diminish to an acute point; the three middle lobes are about six inches long, and two broad in their broadest part; the two next are about an inch shorter, and the two outside lobes are not more than three

inches long; the middle lobes are sinuated on each side near the top, but the two outer are entire. The flowers are produced in umbels at the top of the stalks, these are some male and others female in the same umbel; they are composed of five roundish petals which spread open; the male flowers have their ten stamina joined together in a column, and the female flowers have a roundish germen with three furrows in the center, supporting three styles; two are separated at a distance; and the third arises between them, but is not so long; they are crowned by single stigmas. The germen afterward turns to a roundish capsule with three lobes; each having a distinct cell, containing one seed.

The second sort was discovered by the late Dr. Houstoun at the Havanna, from whence he sent the seeds. This rises with an upright stalk ten or twelve feet high, which is first green and herbaceous, but afterward becomes ligneous, sending out a few branches at the top, which are garnished with smooth leaves, composed of five oval lobes, which end in acute points; the edges are also indented in several irregular points, which are acute. The flowers are produced in an umbel at the extremity of the stalks, they are of an herbaceous white colour, and are male and female in the same umbel, as the other sort; the capsule is smooth and has three cells, each including a single seed.

The third sort was discovered by the late Dr. Houstoun, growing naturally in the sandy grounds about the town of La Vera Cruz, from whence he sent the seeds, which succeeded in the Chelsea garden. This hath a very thick fleshy root, in shape like the white Spanish Radish; the stalk rises from one to two feet high; it is taper, herbaceous, and branching, and closely armed on every side with long white spines, which are not very stiff, but are pungent and stinging; the leaves are divided into five lobes, the middle being the longest; the others are shortened, the two next being about an inch shorter, but the two outer are not more than half the length of the middle; these are deeply jagged on both sides, and are waved on their edges; all the veins of the leaves are closely armed with stinging spines, so that it is dangerous handling them; for all the intermediate parts of the leaves have small stinging spines like those of the Nettle, but they do not appear so visible. At the end of the branches the flowers are produced in umbels; they are white, and have empalements closely armed with the same spines as the stalks and leaves: there are male and female flowers in the same umbel; the female flowers are succeeded by tricapsular vessels, containing three seeds.

The fourth sort rises with an herbaceous stalk about a foot high, dividing into two or three branches, which are garnished with leaves standing alternate upon long foot-stalks; they are composed of three oblong lobes which are slightly sinuated on their edges, ending in acute points; the whole plant is closely armed with long, bristly, stinging spines. The flowers grow in an umbel at the end of the branches; they are small, of a dirty white colour, and are male and female in the same umbel: the female flowers are succeeded by oval capsules with three lobes, which are covered with the same spines as the plant; these have three cells, each containing a single seed. This plant is annual.

The fifth sort was found growing naturally at Carthagen in New Spain, by the late Mr. Robert Millar, who sent the seeds to England, which succeeded in several curious gardens. This hath a thick, swelling, fleshy root, from which arises an herbaceous stalk as big as a man's thumb, which is four or five feet high, and divides into several branches; these are very closely armed with long brown spines; the foot-stalks of the leaves are six or seven inches long, which are also armed with spines, but not so closely, nor are the spines so long as those on the stalk and branches; the leaves are deeply cut into five lobes, which are jagged deeply on their sides, and the nerves are armed with stinging

stinging spines; the flowers are produced in umbels at the top of the branches, standing upon long naked foot-stalks; they are of a pure white colour, and are male and female in the same umbel: the male flowers appear first, which are composed of five petals, forming a short tube at bottom, and the stamina arise the length of the tube, joined in a column: the petals spread open flat above, and the stamina fills the mouth of the tube, shutting it up: the female flowers are smaller, but of the same shape, having no stamina, but an oval three-cornered germen, which afterwards becomes a capsule with three lobes, each having a distinct cell, with one seed inclosed.

The sixth sort was discovered by the late Dr. Houstoun at La Vera Cruz, where it is frequently permitted to grow about the town by way of ornament; this rises with a strong, brittle, ligneous stalk, ten or twelve feet high, covered with a gray bark, and divides into many branches, which are garnished with leaves, that are divided into parts like those of the common Woolfsbane, but are armed with small stinging spines like those of the Nettle; at the end of the branches come out the flower-stalks, which are five or six inches long, sustaining an umbel of white flowers. The male flowers are of one petal, having a pretty long tube, which is divided at the top into five segments. The female flowers expand in form of a Rose, having the germen in the center, which afterward becomes a globular prickly fruit with three lobes, opening in three cells, each containing a single seed.

The seventh sort is now very common in most of the islands in the West-Indies, but was introduced from the continent, first into the French islands, and from thence it was brought into the British islands, where it is titled French Physic Nut, to distinguish it from the following sort, which is called Physic Nut, from its purging quality.

This rises with a soft thick stem eight or ten feet high, dividing into several branches, covered with a grayish bark. The leaves come out on every side the branches on strong foot-stalks, which are seven or eight inches long; they are divided into nine or ten lobes in form of a hand, which are joined at their base; these are seven inches long, and about two inches broad, with many jagged points on their borders standing opposite. The upper side of the leaves are of a lucid green, but their under side gray, and a little cottony. The flowers come out upon long foot-stalks from the end of the branches, formed into an umbel, in which there are male and female flowers, as in the other species; these umbels are large, and the flowers being of a bright scarlet, they make a fine appearance; and the leaves being very remarkable for their beauty, has occasioned the plant being cultivated for ornament in most of the islands of the West-Indies.

The eighth sort grows naturally in all the islands of the West-Indies; this rises with a strong stalk twelve or fourteen feet high, which divides into several branches; these are garnished with angular heart-shaped leaves, which end in acute points. The flowers come out in umbels at the end of the branches; they are male and female, of an herbaceous colour, so make but little appearance; the female flowers are succeeded by oblong oval capsules with three cells, each containing one oblong black seed.

The seeds of the two last sorts have been used as a purgative by the inhabitants of the West-Indies, but they operate so violently, that now they are seldom used; three or four of these nuts have worked upward and downward near forty times, on a person who was ignorant of their effects; but it is affirmed that this purgative quality is contained in a thin film, situated in the center of the nut, which, if taken out, the nuts are harmless, and may be eaten with safety. The leaves of the last sort are used in baths and fomentations.

The ninth sort grows naturally in all the islands of the West-Indies, where it is sometimes called wild

Cassada, or Cassava, and at others Belly-ach Weed, the leaves of this plant being accounted a good remedy for the dry belly-ach. This plant rises with a soft herbaceous stalk to the height of three or four feet, covered with a purple bark, and at the joints have branching bristly hairs rising in small bunches, not only upon the principal stalk, but also on the branches, and the foot-stalks of the leaves. The stalk divides upward into two or three branches; these are garnished with leaves standing on very long foot-stalks, divided into five lobes which are oval, entire, and end in acute points. The flowers are produced at the end of the branches, upon slender naked foot-stalks, in small umbels; they are small, of a dark purple colour, having male and female flowers in the same umbel; the female flowers are succeeded by oblong tricapsular vessels, smooth, and covered with a dark skin, when ripe; in each of the cells is lodged one oblong brown seed.

All these plants are natives of the warm parts of America, so are too tender to thrive in the open air in England. The first sort is cultivated in the West-Indies for food, where it is propagated by cutting the stalks into lengths of seven or eight inches, which, when planted, put out roots; the method of doing this having been mentioned in various books, I shall not repeat it here.

The other sorts are easily propagated by seeds, which should be sown on a good hot-bed in the spring, and when the plants are fit to remove, they should be each transplanted into a small pot filled with light earth, and then plunged into a fresh hot-bed of tanners bark, carefully shading them till they have taken fresh root; after which they must be treated in the same manner as other tender plants from hot countries, admitting fresh air to them daily, in proportion to the warmth of the season; but as many of the sorts have succulent stalks, some of which have a milky juice, they should have but little water given them, for they are soon destroyed by wet.

The fourth sort is an annual plant, so if the seeds are sown early in the spring, and the plants are brought forward, they will perfect their seeds the same year; but the other sorts are perennial, so do not flower till the second or third year; therefore the plants should be plunged into the tan-bed in the stove, where they should constantly remain, giving them a large share of air in warm weather; but in winter they must be tenderly treated, and in that season must have very little water. With this management the plants will continue several years, and produce their flowers, and frequently perfect their seeds in England.

IBERIS. Dillen. Nov. Gen. 6. Lin. Gen. Plant. 721. Thlaspidium. Tourn. Inst. R. H. 214. tab. 101. Sciatica Cress.

The CHARACTERS are,

The flower hath an empalement of four oval leaves, which spread open, are hollowed and fall away. It hath four unequal petals, which are oval, obtuse, and spread open, having oblong erect tails; the two outer petals are longer than the other. It hath six awl-shaped erect stamina, the two on the sides being shorter than the rest, terminated by roundish summits. In the center of the tube is situated a round compressed germen, supporting a short single style, crowned by an obtuse stigma. The germen afterward becomes a roundish compressed vessel, having two cells, each containing one oval seed.

This genus of plants is ranged in the first section of Linnaeus's fifteenth class, intitled Tetrastemonia Siliculosa, which includes those plants whose flowers have four long and two short stamina, and the seeds grow in short pods.

The SPECIES are,

1. IBERIS (*Semperflorens*) frutescens, foliis cuneiformibus obtusis integerrimis. Lin. Hort. Cliff. 330. *Shrubby Sciatica Cress with entire, wedge-shaped, blunt leaves, commonly called the Tree Candy Tuft.* Thlaspidium fruticosum, leucos folio, semperflorens. Tourn. Inst. 214. *Shrubby Thlaspidium with a Gilliflower leaf, always flowering.*

2. *IBERIS* (*Sempervirens*) frutescens foliis linearibus acutis integerrimis. Lin. Hort. Cliff. 330. *Shrubby Scitica Cress with narrow-pointed whole leaves, commonly called Perennial Candy Tuft.* *Thlaspi montanum, sempervirens.* C. B. P. 106. *Evergreen Mountain Candy Tuft.*
3. *IBERIS* (*Umbellata*) herbacea foliis lanceolatis acuminatis, inferioribus serratis, superioribus integerrimis. Lin. Hort. Cliff. 330. *Herbaceous Scitica Cress with spear-shaped pointed leaves, the under ones being sawed, but the upper entire, commonly called Candy Tuft.* *Thlaspi Creticum quibusdam, flore rubente & albo.* J. B. 2. 924. *True Cretan Treacle Mustard with a red and white flower.*
4. *IBERIS* (*Odorata*) foliis linearibus supernè dilatatis serratis. Flor. Leyd. 330. *Scitica Cress with narrow leaves dilated at their top, and sawed.* *Thlaspi umbellatum Creticum, flore albo odoro, minus.* C. B. P. 106. *Small umbellated Treacle Mustard of Crete with a white sweet flower.*
5. *IBERIS* (*Nudicaulis*) herbacea foliis sinuatis, caule nudo simplici. Lin. Hort. Cliff. 328. *Scitica Cress with sinuated leaves, and a single naked stalk.* *Nasturtium petraeum.* Tab. Ic. 451. *Rock Cress.*
6. *IBERIS* (*Amara*) herbacea foliis lanceolatis acutis subdentatis, floribus racemosis. Lin. Hort. Upsal. 184. *Scitica Cress with acute, spear-shaped, indented leaves, and flowers growing in bunches.* *Thlaspi avense umbellatum amarum.* J. B. 2. 925. *Bitter, umbellated, Field Treacle Mustard.*
7. *IBERIS* (*Rotundifolia*) foliis subrotundis crenatis. Royen. Lin. Sp. Plant. 49. *Iberis with roundish crenated leaves.* *Thlaspi Alpinum, folio rotundiore carnosio, flore purpurecente.* Tourn. Inst. 112. *Alpine Treacle Mustard with a rounder fleshy leaf, and a purplish flower.*
8. *IBERIS* (*Linifolia*) frutescens, foliis linearibus acutis, corymbis hemisphaericis. *Shrubby Scitica Cress with narrow acute leaves, and hemispherical bunches of flowers.* *Thlaspi Lusitanicum umbellatum, gramineo folio, purpurecente flore.* Tourn. Inst. R. H. 213. *Portugale, umbellated, Treacle Mustard, with a Grass leaf and a purplish flower.*

The first sort here mentioned is a low shrubby plant, which seldom rises above a foot and a half high, having many slender branches, which spread on every side, and fall toward the ground if they are not supported. These branches are well furnished with leaves toward their extremity, which continue green all the year; and in summer the flowers are produced at the end of the shoots, which are white, and grow in an umbel. These flowers continue long in beauty, and are succeeded by others, so that the plants are rarely destitute of flowers for near eight months, from the end of August to the beginning of June, which renders the plant valuable.

This plant is somewhat tender, therefore is generally preserved in green-houses in winter, where, being placed among other low plants toward the front of the house, it makes an agreeable variety, as it continues flowering all the winter. But although it is commonly so treated, yet in moderate winters this plant will live in the open air, if it be planted in a warm situation and on a dry soil; and if, in very hard frost, they are covered either with mats, Reeds, Straw, or Peas-haulm, they may be preserved very well; and these plants which grow in the full ground, will thrive better, and produce a greater number of flowers, than those which are kept in pots; but the soil in which these are planted, should not be over rich, nor too wet, for in either of these they will grow too vigorous in summer, so will be in greater danger of suffering by the frost in winter; but when they grow on a gravelly soil, or among lime rubbish, their shoots will be short, strong, and not so replete with moisture, so will better resist the cold.

This plant very rarely produces seeds in England, therefore is only propagated by cuttings, which, if planted during any of the summer months, and shaded from the sun, and duly watered, will be rooted in two months, and may afterward be either planted

in pots, or into the borders where they are designed to stand.

There is a variety of this with variegated leaves, which is preserved in some of the gardens where persons delight in these striped-leaved plants. This is not so hardy as the plain sort, therefore must be treated more tenderly in winter; this is also increased by cuttings in the same manner as the other.

The second sort is a plant of humbler growth than the first; this seldom rises more than six or eight inches high, nor do the branches grow woody, but are rather herbaceous; the leaves of this plant continue green through the year, and the flowers are of as long duration as those of the first sort, which renders it valuable. This rarely produces seeds in England, but is propagated by slips, which in summer easily take root, and the plants may be treated in the same manner as hath been directed for the first sort, and will thrive in the open air.

The third sort is a low annual plant, the seeds of which were formerly sown to make edgings for borders in the pleasure-garden, for which purpose all the low annual flowers are very improper, because they do not answer the intent, which is to prevent the earth of the borders falling into the walks, which these plants never can do; and though they make a pretty appearance during their continuance in flower, which is seldom more than a fortnight or three weeks, yet after their flowers are past they become very unsightly; therefore all these sorts of flowers should be sown in small patches in the borders of the flower-garden, where, if they are properly mixed with other flowers, they will have a very good effect; and by sowing of them at three or four different seasons, there may be a succession of them continued in flower till autumn.

There are two different varieties of this third sort, one with red, and the other hath white flowers; but the white is not common in the gardens, but the seeds of the sixth sort are generally sold for it, and is seldom distinguished but by those who are skilled in botany: this plant seldom rises more than five or six inches high, and if they have room will branch out on every side, but when they are left too close, they draw each other up, and are weak: as these do not bear transplanting well, so the seeds should be sown thin in patches, and when the plants are grown pretty strong, they should be thinned, leaving but six or eight in each patch to flower; and by thus treating them, they will put out side branches, and flower much stronger, and continue longer in beauty than when they are left closer together; these plants will require no other culture but to keep them clean from weeds.

The fourth sort seldom grows so large as the third, and the flowers are much smaller, but have an agreeable odour. It grows naturally in Helvetia, and is preserved in botanic gardens for variety. It is annual, and requires the same treatment as the third.

The fifth sort grows on sandy and rocky places in several parts of England, so is rarely admitted into gardens. The leaves of this are small, and cut to the midrib into many jags; these are spread on the ground, and between them arise a naked foot-stalk two or three inches long, sustaining small umbels of white flowers. This is an annual plant, whose seeds should be sown in autumn where the plants are designed to remain, and require no other care but to keep them clean from weeds.

The sixth sort is very like the third, but differs in the shape of the leaves. The flowers of this are white, so may be sown to make a variety with the red. It requires the same treatment.

The seventh sort grows naturally on the Alps, from whence it was sent me; this is a perennial plant, which roots pretty deep in the ground. The lower leaves which rise from the root, are round, fleshy, and crenated on their edges. The stalk rises four or five inches high, and is garnished with small oblong leaves which half embrace the stalks with their base. The flowers terminate the stalk in a round compact

ICE

pect umbel; they are of a purple colour, and appear in June, but are seldom succeeded by seeds in England.

It is propagated by seeds, which should be sown on a shady border in autumn, and when the plants are strong enough to remove, they should be transplanted on a shady border where they are designed to remain, and will require no other care but to keep them clean from weeds.

The eighth sort grows naturally in Spain and Portugal; this hath a great resemblance of the second, but the stalks do not spread so much; they grow erect, about seven or eight inches high, are ligneous and perennial. The leaves are very narrow, and seldom more than an inch long, standing thinly upon the stalks, having no foot-stalks. The flowers grow in hemispherical umbels on the top of the stalks, and are of a purple colour. It flowers in May and June, but seldom produces good seeds here.

This sort may be propagated by cuttings, which should be treated in the same way as is before directed for the first sort; and some of the plants may be planted on a warm border in a dry soil, where they will endure the cold of our ordinary winters very well; but it will be proper to have two or three plants in pots, which may be sheltered under a frame in winter, to preserve the kind, if, by severe frost, those in the open air should be destroyed.

IBISCUS. See **HIBISCUS.**

ICACO. See **CHYRSOBALANUS.**

ICE is a hard transparent body, formed from some liquor congealed, or fixed.

Ice is said to be the natural state of water, which remains firm, and not liquid, when no external cause acts upon it.

The true cause of the congelation of water into Ice, seems to be the introduction of frigorific particles into the pores or interstices between the particles of water, and by that means getting so near them, as to be just within the spheres of one another's attractions, and then they must cohere into one solid or firm body.

It may be wondered why Ice goes to the top of the water, for one would imagine, that being colder than flowing water, it ought to be more condensed, and consequently heavier; but is to be considered, that there are always some bubbles of air interspersed in Ice. It is certain, by the swimming of Ice upon water, that it is specifically lighter than the water out of which it is made by freezing; and it is as certain, that this lightness of Ice proceeds from those numerous bubbles that are produced in it by congelation.

Water, when it is frozen into Ice, takes up more space than it did before it was congealed. It is visible, that the dimensions of water are increased by freezing, its particles being kept at some distance the one from the other, by the intervention of the frigorific matter.

And, besides, there are many little volumes of air included at several distances, both in the pores of the watery particles, and in the interstices made by the spherical figures. Now, by the insinuation of these chrystals, the volumes of air are driven out of the watery particles, and many of them uniting, form larger volumes; these have thereby a greater force to expand themselves than when they are dispersed, and so both enlarge their dimensions, and lessen the specific gravity of water thus congealed into Ice.

It seems very probable, that cold, and freezing, and consequently Ice, are produced by some substance of a saline nature floating in the air; in that salts, and more eminently some particular ones, when mixed with Ice or snow, do wonderfully increase the force and effects of cold.

It is also visible, that all saline bodies cause a stiffness and frigidity in those bodies into which they enter.

It is manifest, by observing salts by microscopes, that the figures of some salts, before they shoot into

ICE

masses, are then double wedge-like particles, which have abundance of surface in respect to their solidity; and this is the reason why they swim in water, when once they are raised in it, although they are specifically heavier, these small points of salts getting into the pores of the water, whereby they are, in some measure, suspended in the winter, when the heat of the sun is not ordinarily strong enough to dissolve the salts into fluid, to break their points, and to keep them in perpetual motion; which being less disturbed, are more at liberty to approach one another, and by shooting into chrystals, of the form above-mentioned, do, by their extremities, insinuate themselves into the pores of water, and by that means freeze it into a solid form, called Ice.

Mons. Mariotte, in his Treatise of Hydrostatics, gives the subsequent account of what happens to water in freezing, which he discovered by the following experiment.

Having filled a cylindric vessel, of about seven or eight inches high, and six inches diameter, within two inches of the top, with cold water, he exposed it to the open air in a great frost, and observed exactly the whole progress of the freezing of it.

The first congelation was in the upper surface of the water, in little long water shoots, or laminae, which were jagged like a saw, the water between them remaining still unfrozen, though the rest of the surface was already frozen to the thickness of more than two lines; he observed that several bubbles of air were formed in the Ice, that began to fix on the bottom and sides of the vessel, some would rise up, and others remained entangled in the Ice, which made him imagine that these bubbles taking up more space in the water, than when their matter was, as it were, dissolved in it, they pushed up a little water through the hole at the top, after the same manner that new wine works out at the bung-hole of a vessel when it begins to heat, and the little water that oozed out at this little hole in the Ice, spreading itself upon the upper surface of the water, which was already frozen, became Ice also, and there began to form a hill of Ice; and that hole continuing open, by reason of the water which passed successively through it, being pushed up by the new bubbles which formed themselves in the Ice, which continue to increase about the sides and bottom of the vessel, he observed that the upper surface of the water was frozen above an inch thick towards the edges of the vessel, and above an inch and a half round about the little hole, before the water that was contained in it, as in a pipe, became frozen, but at last it was frozen; then the middle of the water remaining unfrozen, and the water which was compressed by the new bubbles, which formed themselves for two or three hours, having no vent at the little hole, the Ice broke at once towards the top, by the spring of the included air.

In like manner the frost acts upon vegetables, by these frigorific particles entering the tender shoots of plants, and insinuating between the pores of the sap, thereby increasing its bulk, so that the tender vessels of the plants are torn, and those parts of the plants are soon killed; and the greater the quantity of moisture is in vegetables, the more they are in danger of being destroyed, for we frequently see many plants which grow on the top, and from the joints of walls, escape the severest frosts, when those of the same kinds are all destroyed which were in the ground; which is entirely owing to their vessels being stronger and more compact, and not so replete with moisture: so when the autumn proves cold and moist, whereby the vessels of plants are not properly hardened, and are replete with moisture, a small frost will do great mischief to them; whereas when the autumn is dry and warm, the tender shoots of trees and shrubs are hardened, and drained of their moisture, so are not liable to the like accidents.

ICE-HOUSE is a building contrived to preserve ice for the use of a family in the summer season.

These

ICE

These are more generally used in warm countries, than in England, but particularly in Italy, where the meanest person who rents a house, is not without a vault or cellar for keeping of ice; but as the use of ice in England is much greater of late than it was formerly, so the number of Ice-houses has been greatly increased; and although the mention of these may, at first sight, seem foreign to my subject, yet if it is considered, that these buildings are generally erected in gardens, and as often put under the care of gardeners, it may not be amiss for me to give some general directions for the choice of the situation and structure of the building, as also for the management of the ice.

In the choice of a situation for an Ice-house, the principal regard should be, that of a dry spot of ground, for wherever there is moisture, the ice will melt; therefore in all strong lands, which detain the wet, there cannot be too much care taken to make drains all round the building to carry off all moisture; for when this is lodged near the building, it will occasion a damp there, which will always be prejudicial to the keeping of the ice.

The next consideration must be, to have the place so elevated, that there may be descent enough to carry off whatever wet may happen near the building, or from the ice melting; also, that the place be as much exposed to the sun and air as possible, and not placed under the drip, or in the shade of trees, as hath been too often practised, under a false notion, that if it should be exposed to the sun, the ice will melt away in summer, which never can be the case where there is sufficient care taken to exclude the outward air (which must always be regarded in the building of these houses) for the heat of the sun can never penetrate through the double arches of the building, so as to add any warmth to the air; but when the building is entirely open to the sun and wind, all damps and vapours will thereby be removed from about the building, which can never be kept too dry, or free from moist vapours. As to the figure of the building, that may be according to the fancy of the owner; but for the well into which the ice is to be put, a circular figure is the most convenient; the depth of the well, as also the diameter of it, must be proportioned to the quantity of ice wanted, but it is always best to have enough; for when the house is well built, it will keep the ice for two or three years; and there will be this advantage in having it large enough to contain ice for two years consumption, that if a mild winter should happen, when there is not ice to be had, there will be a stock to supply the want.

If the quantity wanting is not great, a well of six feet diameter, and eight feet deep, will be large enough; but for large consumption, it should not be less than nine or ten feet diameter, and as many deep: where the situation is either dry chalk, gravel, or sand, the pit may be entirely below the surface of the ground; but in strong loam, clay, or moist ground, it will be the best way to raise it so high above the surface, as that there may be no danger from the wet.

At the bottom of the well there should be a space left, about two feet deep, to receive any moisture which may drain from the ice, and a small underground drain should be laid from this, to carry off the wet; over this space of two feet, should be placed a strong grate of wood, to let the moisture fall down, which may at any time happen, from melting of the ice. The sides of this well must be bricked up with a wall, at least two bricks and a half thick; but if it is yet thicker, it will be better, because the thicker the walls are made, the less danger there will be of the well being affected by any external cause. When the well is brought within three feet of the surface, there must be another outer arch or wall begun, which must be carried up to the height of the top of the intended arch of the well; and if there is a second arch turned over from this well, it will add to the goodness of the house; but this must be submitted to the

JET

person who builds, if he will be at the expence; but if not, then the plate into which the roof is to be framed, must be laid on this outer wall, which should be carried high enough above the inner arch, to admit of a door-way in, to get out the ice. If the building is to be covered with slates or tiles, there should be a thickness of Reeds laid under, to keep out the sun and external air; if these Reeds are laid two feet thick, and plastered over with lime and hair, there will be no danger of the heat getting through it.

The external wall need not be built circular, but of any other figure, either square, hexangular, or octangular; and where this stands much in sight may be so contrived as to make it a good object. I have seen an Ice-house built in such a manner as to have a handsome alcove seat in the front, and behind this seat was contrived a passage to get out and put in the ice; and by having the entrance behind, to the north aspect, a small passage being next the seat, through which a person might enter to take out the ice, and a large door being contrived with a porch, wide enough for a small cart to back in, to shoot down the ice upon the floor near the mouth of the well, where it may be well broken, before it is put down. The aperture of this mouth of the well need not be more than two feet and a half diameter, which will be large enough to put down the ice, and if it was greater, it would be inconvenient; there should be a stone fitted to stop this aperture, which must be closed up as secure as possible, after the ice is put in, and all the vacant space above and between this and the outer door, must be filled close with Barley Straw, to exclude the air; so the door to enter for taking out the ice should be on the opposite side, immediately behind the alcove seat, as was before-mentioned; and this door should be no larger than is absolutely necessary for the coming at the ice, and must be strong and close to exclude the air; and at five or six feet distance from this another door should be contrived, which should be closely shut before the inner door is opened, whenever the ice is taken out.

The building being finished, should have time to dry before the ice is put into it; for when the walls are green, the damp of them frequently melts the ice. At the bottom of the well, upon the wooden grate, should be laid some small faggots; and if upon these a layer of Reeds is placed smooth for the ice to lie upon, it will be better than Straw, which is commonly used; and in the choice of the ice, the thinner it is, the better it may be broken to powder; for the smaller it is broken, the better it will unite when put into the well: in putting of it in, there must be care taken to ram it close, as also to allow a vacancy all round next the wall, of about two inches; this is to give passage to any moisture, which may be occasioned by the melting of some of the ice on the top, which, if pent up, will melt the ice downward; when the ice is put into the well, if there is a little salt-petre mixed at every ten inches or a foot thickness, it will cause the ice to join more closely into a solid mass. The instructions here given, being carefully observed, will be sufficient to guide persons wholly ignorant in these matters.

JET D'EAU is a French word, which signifies a fountain that casts up water to any considerable height in the air.

Mons. Mariotte, in his Treatise of Hydrostatics, says, That a Jet d'Eau will never rise so high as its reservoir, but always falls short of it by a space which is in a subduplicate ratio of that height; and this he proves by several experiments; that though Jets ought to rise to the height of the reservoirs, yet the friction of the sides of the ajutages, and the resistance of the air, are the causes that in Jets that have very high reservoirs, the height of the Jets does not come up to that of the reservoir by a great deal.

He adds, That if a greater branches out in many smaller ones, or is distributed through several Jets, the square of the diameter of the main pipe must be proportioned

portioned to the sum of all the expences of its branches; that if the reservatory be fifty-two high, and the ajutages half an inch in diameter, the pipe ought to be three inches in diameter.

He says, That the beauty of Jets of water consists in their uniformity and transparency at the going out of the ajutage, and spreading but very little, and that to the highest part of the Jet.

That the worst sort of ajutages are those that are cylindrical, for they retard very much the height of the Jets, the conic retard it less; but the best way is, to bore the horizontal plane, which shuts the extremity of the pipe, or conduit, with a smooth and polished hole, taking care that the plate be perfectly plain, polished, and uniform.

These spouts of water are some of the greatest beauties of the Italian gardens, and are certainly better adapted for gardens in those warm countries, than they are for our climate, because, in the great heats of summer, the sight of these water-spouts is cooling and refreshing to the imagination, and they certainly add a real coolness to the air; but in cold countries they cool the air too much, therefore should not be erected; or if they are, they should be placed at such distances from the habitation, as that the damp may no ways affect it.

Where these Jets are contrived, if there is not a constant supply for a large column of water, they should by no means be made, for nothing can have a meaner appearance, than those pitiful pissing spouts, so frequently to be seen in England, which perhaps have not a supply of water to play above an hour or two; therefore where there is not a natural body of water, to supply these Jets, without the expence of raising it, there should never be any of these contrived in gardens.

I L E X. Lin. Gen. Plant. 158. Aquifolium. Tourn. Inst. R. H. 600. tab. 371. The Holly-tree; in French, *Houx*.

The CHARACTERS are,

They have male, female, and hermaphrodite flowers on different plants. The male flowers have a small permanent empalement of one leaf, which is indented in four parts; they have but one petal, which is cut into four segments almost to the bottom; they have four owl-shaped stamina, which are shorter than the petal, and are terminated by small summits. The female flowers have their empalements and petals the same as the male, but have no stamina; in their center is placed the roundish germen, having four obtuse stigmas sitting on it. The germen afterward becomes a roundish berry with four cells, each containing a single hard seed.

This genus of plants is ranged in the third section of Linnaeus's fourth class, intitled Tetrandria Tetragynia, which includes those plants whose flowers have four stamina and four styles; but according to his own system, it should be placed in the third section of his twenty-second class, with those plants which have male and hermaphrodite flowers on different plants.

The SPECIES are,

1. ILEX (*Aquifolium*) foliis oblongo-ovatis, undulatis, spinis acutis. *Holly-tree with oblong leaves which are waved, and have acute spines. Ilex aculeata baccifera.* C. B. P. 425. *Prickly berry-bearing Ilex*; and the *Aquifolium* five *agrifolium* vulgò. J. B. 1. 114. *The common Holly.*
2. ILEX (*Echinata*) foliis ovatis, undulatis, marginibus aculeatis, paginis supernè spinosis. *Holly with oval waved leaves, whose borders are armed with strong thorns, and their upper surface prickly. Aquifolium echinata folii superficie.* Cornut. Canad. 180. *Holly-tree whose upper surface of the leaves are prickly, commonly called Hedge-hog Holly.*
3. ILEX (*Caroliniana*) foliis ovato-lanceolatis serratis. Hort. Cliff. 40. *Holly with oval, spear-shaped, sawed leaves. Aquifolium Caroliniense, foliis dentatis, baccis rubris.* Catesb. Carol. 1. p. 31. *Carolina Holly with indented leaves and red berries, commonly called Daboon Holly.*

There are several varieties of the common Holly with variegated leaves, which are propagated by the nursery gardeners for sale, and some years past were in very great esteem, but at present are but little regarded, the old taste of filling gardens with shorn Evergreens being pretty well abolished; however, in the disposition of the clumps or other plantations of Evergreen trees and shrubs, a few of the most lively colours may be admitted, which will have a good effect in the winter season, if they are properly disposed.

As the different variegations of the leaves of Hollies, are by the nursery gardeners distinguished by different titles, so I shall here mention the most beautiful of them, by the names they are generally known.

Painted Lady Holly, British Holly, Bradley's best Holly, Phyllis, or Cream Holly, Milkmaid Holly, Pritchett's best Holly, Gold-edged Hedge-hog Holly, Cheyney's Holly, Glory of the West Holly, Broadrick's Holly, Partridge's Holly, Herefordshire white Holly, Blind's Cream Holly, Longstaff's Holly, Eales's Holly, Silver-edged Hedge-hog Holly.

All these varieties are propagated by budding or grafting them upon stocks of the common green Holly: there is also a variety of the common Holly with smooth leaves, but this is frequently found intermixed with the prickly-leaved on the same tree, and often on the same branch, there are both sorts of leaves.

The common Holly grows naturally in woods and forests in many parts of England, where it rises from twenty to thirty feet high, and sometimes more, but their ordinary height is not above twenty-five feet. The stem by age becomes large, and is covered with a grayish smooth bark; and those trees which are not lopped or browzed by cattle, are commonly furnished with branches the greatest part of their length, so form a sort of cone; the branches are garnished with oblong oval leaves about three inches long, and one and a half broad, of a lucid green on their upper surface, but are pale on their under, having a strong midrib: the edges are indented and waved, with sharp thorns terminating each of the points, so that some of the thorns are raised upward and others are bent downward, and being very stiff, renders them troublesome to handle. The leaves are placed alternate on every side of the branches, and from the base of their foot-stalks come out the flowers in clusters, standing on very short foot-stalks; each of these sustain five, six, or more flowers. In some plants I have observed the flowers were wholly male, and produced no berries; in others I have observed female and hermaphrodite flowers, but upon some large old trees growing on Windsor forest, I have observed all three upon the same trees. The flowers are of a dirty white, and appear in May; they are succeeded by roundish berries, which turn to a beautiful red about Michaelmas, but continue on the trees if they are not destroyed, till after Christmas before they fall away.

The second sort grows naturally in Canada, from whence it was brought to Europe. The leaves of this sort are not so long as those of the common Holly, and their edges are armed with stronger thorns standing closer together; the upper surface of the leaves is set very close with short prickles, from whence the gardeners have given it the title of Hedge-hog Holly. This sort is usually propagated in the nurseries, by budding or grafting it upon the common Holly; but I have raised it from the berries, and found the plants to be the same as those from whence the seeds were taken, so make no doubt of its being a distinct species.

There are two varieties of this with variegated leaves, one of which is yellow, and the other white. There is also a variety of the common Holly with yellow berries, which is also accidental, and is generally found on those plants which have variegated leaves, and but seldom on plain Hollies.

The common Holly is a very beautiful tree in winter, therefore deserves a place in all plantations of

Evergreen trees and shrubs, where its shining leaves and red berries make a fine variety; and if a few of the best variegated kinds are properly intermixed, they will enliven the scene. The Holly was also formerly planted for hedges, and is a very proper plant for that purpose; but then it should not be clipped with shears, because when the leaves are cut through the middle, they are rendered unsightly, so they should be cut with a knife close to the leaf; and although in this method they are not shorn so even as with shears, yet they will have a much better appearance, and may be made as close and secure as by any other method generally practised.

The Holly is propagated by seeds, which never come up the first year, but lie in the ground as the Haws do; therefore the berries should be buried in the ground in a large pot or tub one year, and then taken up and sown in the autumn upon a bed exposed only to the morning sun; the following spring the plants will appear, which must be kept clean from weeds; and if the spring should prove dry, it will be of great service to the plants if they are watered once a week; but they must not have it oftener, nor in too great quantity, for too much moisture is very injurious to these plants when young.

In this seed-bed the plants may remain two years, and then should be transplanted in the autumn, into beds at about six inches distance each way, where they may stand two years longer, during which time they must be constantly kept clean from weeds; and if the plants have thriven well, they will be strong enough to transplant where they are designed to remain; for when they are transplanted at that age, there will be less danger of their failing, and they will grow to a larger size than those which are removed when they are much larger; but if the ground is not ready to receive them at that time, they should be transplanted into a nursery in rows at two feet distance, and one foot asunder in the rows, in which place the plants may remain two years longer; and if they are designed to be grafted or budded with any of the variegated kinds, that should be performed after the plants have grown one year in this nursery; but the plants so budded or grafted should continue two years after in the nursery, that they may make good shoots before they are removed; though the plain ones should not stand longer than two years in the nursery, because when they are older, they do not transplant so well. The best time for removing of Hollies is in the autumn, especially in dry land; but where the soil is cold or moist, they may be transplanted with great safety in the spring; if the plants are not too old, or if they have not stood long unremoved, there is great odds of their dying when removed.

The Dahoon Holly grows naturally in Carolina, from whence the seeds were sent by the late Mr. Mark Catesby, who found the trees growing on a swamp at a distance from Charles-town, but it hath since been discovered in some other countries in North America. This rises with an upright branching stem to the height of eighteen or twenty feet; the bark of the old stems is of a brown colour, but that of the branches or younger stalks is green and smooth, garnished with spear-shaped leaves, which are more than four inches long, and one and a quarter broad in the broadest part, of a light green and thick consistence; the upper part of the leaves are sawed on their edges, each serrature ending in a small sharp spine; they stand alternately on every side the branches, upon very short foot-stalks. The flowers come out in thick clusters from the side of the stalks; they are white, and shaped like those of the common Holly, but are smaller; the female and hermaphrodite flowers are succeeded by small roundish berries in its native country, which make a fine appearance in winter, but they have not as yet produced fruit in England, so far as I can learn.

Dr. Linnæus supposes this plant and the evergreen Cassine to be the same, but they are undoubtedly dif-

ferent plants: he may probably have been led into this mistake, by receiving seeds of this sort mixed together with the berries of Cassine from America, which I have more than once done; but whoever sees the two plants growing, cannot doubt of their being different.

This sort is tender while young, so requires protection in the winter till the plants are grown strong and woody, when they may be planted in the full ground in a warm situation, where they will endure the cold of our ordinary winters pretty well; but in severe frost they should be protected, otherwise the cold will destroy them.

This sort is propagated from seeds, in like manner as the common sort; the seeds of it will lie as long in the ground, so the berries should be buried in the ground a year, and then taken up and sown in pots filled with light earth, and placed under a frame in winter; in the spring the pots should be plunged into a hot-bed, which will bring up the plants; these must be preserved in the pots while young, and sheltered in winter under a common frame till they have obtained strength, when in the spring they may be turned out of the pots and planted in the full ground, in a warm situation.

From the bark of the common Holly is made the bird-lime, and the wood is made into hones for setting of razors. The wood is very white, and takes a fine polish, so is very proper for several kinds of furniture. I have seen a floor of a room laid in compartments with Holly and Mahogany, which had a very pretty effect.

ILLECEBRUM. Lin. Gen. 291. Corrigiola. Dill. Gen. p. 169. Paronychia. Tourn. Inst. 281.

The CHARACTERS are,

It hath a five-cornered coloured empalement of five leaves, which is permanent, but has no petals; it hath five slender stamina within the empalement, terminated by simple summits, and an oval germen with a short style, crowned by an obtuse stigma. The empalement afterward becomes a roundish capsule with five angles, having one cell, containing one large seed, which is pointed on every side.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, the flowers having five stamina and one style.

The SPECIES are,

1. **ILLECEBRUM** (*Suffruticosum*) floribus lateralibus solitariis, caulibus suffruticosus. Lin. Sp. 298. *Illecebrum with an under-shrub stalk, having single flowers on the sides.* Paronychia Hispanica fruticosa, myrti folio. Tourn. Inst. 508.
2. **ILLECEBRUM** (*Paronychia*) floribus bracteis nitidis obvalatis, caulibus procumbentibus. Lin. Sp. 299. *Illecebrum with neat bractea inclosing the flowers, and trailing stalks.* Paronychia Hispanica. Clus. Hist. 2. p. 183.
3. **ILLECEBRUM** (*Capitatum*) floribus bracteis nitidis occultantibus capitula terminalia, caulibus erectis, foliis ciliatis. Lin. Sp. 299. *Illecebrum with neat bractea terminating the erect stalks, and silvery leaves.* Paronychia Narbonensis erecta. Tourn. Inst. 508.
4. **ILLECEBRUM** (*Achyrantha*) caulibus repentibus pilosis, foliis ovatis mucronatis opposito minore, capitulis subglobosis subspinosis. Lin. Sp. 299. *Illecebrum with creeping stalks, small oval-pointed leaves placed opposite, almost globular heads of flowers, having small spines.* Achyrantha repens, foliis bliti pallidi. Hort. Elth. 8. tab. 7.
5. **ILLECEBRUM** (*Polygonoides*) caulibus repentibus hirtis, foliis lato-lanceolatis petiolatis, capitulis orbiculatis nudis. Lin. Sp. 300. *Illecebrum with hairy creeping stalks, broad spear-shaped leaves on foot-stalks, and orbicular naked heads of flowers.* Amaranthoides humile Curassavicum, foliis polygoni. Herm. Parad. 17.
6. **ILLECEBRUM** (*Vermiculatum*) caulibus repentibus glabris foliis, subteretibus carnosiss, capitulis oblongis glabris terminalibus. Lin. Sp. 300. *Illecebrum with smooth creeping stalks, almost taper fleshy leaves, and oblong smooth heads terminating the branches.* Amaranthoides humile Curassavicum, cepeæ foliis lucidis, capitulis. Herm. Parad. 15.

The

I M P

The three first sorts grow naturally in Spain, Portugal, and the south of France; the first has ligneous stalks about a foot high, garnished with small leaves like those of Knot-grass; the flowers come out singly on the side of the stalks, which make little appearance, so is seldom preserved in gardens.

The second and third sorts have trailing stalks near two feet long, which spread on the ground, garnished with leaves like those of the first sort; the heads of flowers come out from the joints of the stalk, having neat silvery bractea surrounding them, which make a pretty appearance. Their flowers appear in June, and there is generally a succession of them for at least two months; and when the autumn proves warm, they will ripen their seeds the beginning of October.

These three sorts may be propagated by seeds, which should be sown on a bed of light earth the beginning of April; the plants will come up in May, when they should be kept clean from weeds till the plants are fit to remove; then the plants should be carefully taken up, planting some of each sort in small pots, and the other into a warm dry border, observing to water and shade them until they have taken new root; after which, those which are planted in the full ground will require no other culture but to keep them clean from weeds; for in the ordinary winters of England, they will live in the open air: but as these plants are sometimes killed in severe winters, therefore I advise some plants to be planted in pots, which may be placed in a common frame in winter, where they may enjoy the open air in mild weather, but be screened from frost.

As the seeds of these plants do not constantly ripen in England, so they may be propagated by cuttings, which, if carefully taken off in May or June, and planted in a shady border, will in two months put out roots; then in moist weather they may be transplanted, and afterward treated as the old plants.

The other three sorts are natives of the warm parts of America; the fourth sort grows naturally at Beunos Ayres; the fifth and sixth, in many of the islands in the West-Indies.

These have creeping stalks, which send out roots from the joints, which fasten to the ground in their native soil, whereby they spread to a great distance; and in this country, when the pots are plunged into a tan-bed, they will multiply as fast, by taking root in tan, or any of the other pots of plants which are near them.

The flowers of the fourth sort make little appearance, therefore the plant is rarely propagated, except in botanic gardens for variety; but those of the fifth and sixth sort have dry heads of flowers, resembling those of the *Amaranthoides*, under which genus they were formerly ranged.

These three sorts are tender, so will not thrive in the open air in England; therefore their seeds should be sown on a hot-bed in the spring, at the same time as the *Amaranthus*, *Gomphrena*, and other tender plants; and afterward, if they are plunged into the tan-bed in the stove, their branches will put out roots, whereby they may be propagated in plenty.

IMPATIENS. Rivin. Ord. 4. Lin. Gen. Plant. 899. *Balsamina*. Tourn. Inst. R. H. 418. tab. 235. Female Balsamine; in French, *Balsamine*.

The CHARACTERS are,

The flower has a two-leaved small empalement, which is coloured, and placed on the side of the petals. It hath five petals which are unequal, and shaped like a lip-flower; the petals are roundish, the upper is erect, slightly cut at the point into three parts, where it is sharp-pointed, forming the upper lip; the two lower petals are broad, obtuse, irregular, and reflexed; these constitute the lower lip; the intermediate pair are alike, and are placed opposite, joining at their base. It hath a nectarium in the bottom of the flower, shaped like a hood or cowl, which is oblique to the mouth, rising on the outside, whose base ends in a tail or spur. It hath five short stamina which are narrow toward their base, and incurved, terminated by

I M P

summits, which join at the top round the stamina, but are divided at their base. In the bottom is situated an oval sharp-pointed germen, having no style, but a single stigma shorter than the summits. The germen afterward becomes a capsule with one cell, opening with an elasticity in five valves, which twist spirally, and contain several roundish seeds fixed to a column.

This genus of plants is ranged in the fifth section of Linnæus's nineteenth class, which includes those plants which have single flowers in the empalement, whose stamina vary in number and situation.

The SPECIES are,

1. **IMPATIENS** (*Noli tangere*) pedunculis multifloris solitariis, foliis ovatis, geniculis caulinus tumentibus. Flor. Suec. 722. *Impatiens* with foot-stalks sustaining many single flowers, oval leaves, and stalks having swelling joints. *Balsamina lutea*, five, *Noli me tangere*. C. B. P. 306. *Yellow Balsamine*, or *Touch me not*.
2. **IMPATIENS** (*Balsamina*) pedunculis unifloris aggregatis, foliis lanceolatis, nectaris floribus brevioribus. Hort. Upsal. 276. *Impatiens* with foot-stalks sustaining single flowers, which arise in clusters, spear-shaped leaves, and nectariums which are shorter than the flower. *Balsamina fœmina*. C. B. P. 306. *The female Balsamine*.
3. **IMPATIENS** (*Triflora*) pedunculis trifloris solitariis, foliis angusto-lanceolatis. Flor. Zeyl. 315. *Impatiens* with three flowers on a foot-stalk, and narrow spear-shaped leaves. *Balsamina erecta*, sc. *fœmina*, *Perficæ angusto folio Zeylanica*. Herm. Par. Bat. 105. *Upright*, or *female Balsamine of Ceylon*, with a narrow Peach leaf.

There are several other species of this genus, which grow naturally in India, which are plants of little beauty, so have not been introduced into the English gardens; the sorts here mentioned, are all I have yet seen growing here, except one tall sort from North America.

The first sort grows naturally in several parts of Westmoreland and Yorkshire, but is frequently introduced into gardens by way of curiosity. It is an annual plant, which rises about a foot and a half high, with an upright succulent stalk, whose joints are swollen, garnished with oval smooth leaves, which stand alternate on every side the stalk. The flowers come out from the wings of the stalks upon long slender foot-stalks, which branch into several other smaller, each sustaining one yellow flower, composed of five petals, which in front are shaped like the lip or grinning flowers, but at their base have a nectarium with a long tail like the flowers of Indian Cress; these are succeeded by taper pods, which, when ripe, burst open upon being touched, and twist spirally like a screw, casting out the seeds with great elasticity. If the seeds of this plant are permitted to scatter, they generally succeed better than when they are sown; for unless they are sown in the autumn soon after they are ripe, they very rarely grow. The plants require no care but to keep them clean from weeds, and thin them where they are too close. It flowers in June, and the seeds ripen about a month or five weeks after; this delights in a shady situation and a moist soil.

The second sort is the female Balsamine, of which there are several varieties; the common sort has been long an inhabitant in the English gardens, of this there is the white, the red, and striped flowered, and likewise the single and double flowering, with variegated flowers of two colours. These sorts are so hardy as to rise in the full ground; and where the seeds scatter, the plants will come up the following spring; but such self-sown plants do not come to flower so early as those which are raised upon a hot-bed; however, they generally are stronger plants, and continue much longer in the autumn in flower than the others, so are an ornament to the garden, when there is a greater scarcity of flowers.

This sort rises a foot and a half high, dividing into many succulent branches, which are garnished with long, spear-shaped, sawed leaves. The flowers come out from the joints of the stalks, upon slender foot-stalks

stalks about an inch long, each sustaining a single flower; but there are two, three, or four of these foot-stalks arising from the same joint. The flowers are composed of five large unequal petals, which are shaped like those of the former sort, but are larger, and spread open much wider; there are white, purple, and red of this sort, as also single and double flowers. If the seeds of these are sown on a moderate hot-bed in the spring, the plants will flower in June; but those which are sown in the full ground, will not flower before the middle of July; and these will continue flowering till the frost puts a stop to them in the autumn.

There are two other varieties of this, if not distinct species; one of them grows naturally in the East, and the other in the West-Indies; that which comes from the East-Indies, by the title of Immortal Eagle Flower, is a most beautiful plant; the flowers are double, much larger than those of the common sort; they are scarlet and white variegated, and purple and white in others; and the plants producing many flowers, render them very valuable; and if the seeds of these are carefully saved, the kinds may always be preserved; but I have raised some plants from foreign seeds, whose flowers were so very double as to lose their male parts, so did not produce any seeds.

The seeds of these plants should be sown on a moderate hot-bed in the spring, and when the plants are come up about an inch high, they should be transplanted on another moderate hot-bed at about four inches distance each way, observing to shade them from the sun till they have taken new root; after which they should have a large share of free air admitted to them, at all times when the weather is favourable, to prevent their drawing up tall and weak: they will require to be often refreshed with water, but it should not be given to them in too great plenty; for as their stems are very succulent, so they are apt to rot with much moisture. When the plants are grown so large as to touch each other, they should be carefully taken up with balls of earth to their roots, and each planted into a separate pot filled with light rich earth, and plunged into a very moderate hot-bed under a deep frame, to admit the plants to grow, shading them from the sun until they have taken fresh root; then they should have a large share of air admitted to them every day, and by degrees hardened, so as to bear the open air, into which part of the plants may be removed in July, placing them in a warm sheltered situation; where, if the season proves favourable, they will flower and make a fine appearance; but it will be proper to keep part of the plants either in a glass-case or a deep frame, in order to get good seeds, because those in the open air will not ripen their seeds unless the summer proves very warm; and the plants in shelter must have a good share of free air every day, otherwise they will grow pale and sickly; nor should they have too much of the sun in the middle of the day, in very hot weather, for that occasions their leaves hanging and their requiring water, which is often very hurtful; therefore if the glasses are shaded in the middle of the day for three or four hours, the plants will thrive better, and continue longer in beauty than when they are exposed to the great heat. Those who are curious to preserve these plants in perfection, pull off all the single and plain coloured flowers from the plants which they preserve for seeds, leaving only those flowers which are double and of good colours; where this is carefully done, they may be continued without the least degeneracy constantly.

The sort which grows in the West-Indies, is there called Cockspur. This hath single flowers as large as the last-mentioned sort, but I never saw any of them more than half double, and only with white and red stripes: the plants are very apt to grow to a very large size before they produce any flowers, so that it is late in the autumn before they begin to flower; and sometimes in bad seasons they will scarce have any flowers,

and but rarely ripen their seeds here, so that few persons care to cultivate this sort, especially if they can have the other.

The third sort here mentioned grows naturally in Ceylon, and in many parts of India; this hath very narrow spear-shaped leaves, which are sawed on their edges; the foot-stalks sustain each three flowers, which are smaller than those of the common sort, so are not worthy of a place in gardens, except for the sake of variety. This is a tender plant, and requires the same treatment as the Immortal Eagle Flower.

IMPERATORIA. Lin. Gen. Plant. 321. Tourn. Inst. R. H. 316. tab. 168. Masterwort; in French, *Imperatoire*.

The CHARACTERS are,

It hath an umbellated flower; the principal umbel is plain, and composed of many smaller; the greater umbel has no involucre, but the small ones have, which are composed of many narrow leaves, almost as long as the umbel; the principal umbel is uniform; the flowers have five heart-shaped petals, which are equal and inflexed. They have five hairy stamina, terminated by roundish summits. The germen is situated under the petals, supporting two reflexed styles, crowned by obtuse stigmas. The germen afterward becomes a roundish compressed fruit divided in two parts, containing two oval-bordered seeds.

This genus of plants is ranged in the second section of Linnaeus's fifth class, intitled Pentandria Digynia, which contains the plants whose flowers have five stamina and two styles.

We have but one SPECIES of this genus, viz.

IMPERATORIA (*Ostruthium*.) Hort. Cliff. 103. *Masterwort*. Imperatoria major. C. B. P. 150. *Greater Masterwort*; and the Atlantia of Dodonæus. Pempt. 320. *Masterwort, or false Pellitory of Spain*.

This plant grows naturally on the Austrian and Styrian Alps, and upon other mountainous places in Italy; the root is as thick as a man's thumb, running obliquely in the ground; it is fleshy, aromatic, and has a strong acrid taste, biting the tongue and mouth like Pellitory of Spain; the leaves arise immediately from the root; they have foot-stalks seven or eight inches long, dividing into three very short ones at the top, each sustaining a trilobate leaf, indented on the border; the foot-stalks are deeply channelled, and when broken emit a rank odour. The flower-stalks rise about two feet high, and divide into two or three branches, each being terminated by a pretty large umbel of white flowers, whose petals are split; these are succeeded by oval compressed seeds, somewhat like those of Dill; but larger. It flowers in June, and the seeds ripen in August.

This plant is cultivated in gardens to supply the markets. It may be propagated either by seeds, or by parting the roots: if you would propagate it by seeds, they should be sown in autumn soon after they are ripe, on a bed or border, in a shady situation; observing not to sow the seeds too thick, nor should they be covered too-deep. In the spring the plants will appear, when they should be carefully weeded; and if the season should prove very dry, they should be now and then refreshed with water, which will greatly promote their growth. Toward the beginning of May, if you find the plants come up too close together, you should prepare a moist shady border (and thin the plants carefully, leaving them about six inches asunder;) and plant those which you draw up into the border about the same distance apart every way, being careful to water them duly, if the season should prove dry, until they have taken root; after which time, these plants (as also those remaining in the seed-beds) will require no other culture but to keep them clear from weeds; which may be easily effected, by hoeing the ground between the plants now and then in dry weather, which will destroy the weeds; and by thus stirring the ground, will be of great service to the plants. The following autumn these plants should be transplanted where they are designed to remain, which should be in a rich moist soil and a shady situation;

tation; where they will thrive much better than if too much exposed to the sun, or in a dry soil, for they delight in shade and moisture; so that where these are wanting the plants will require a constant supply of water in dry weather, otherwise they will thrive but slowly. The distance which these plants should be placed, must not be less than two feet every way, for where they like their situation, they will spread and increase much. When these plants are rooted, they will require no other culture but to keep them clear from weeds; and in the spring, before they shoot, the ground should be every year gently dug between the plants; in doing of which, great care should be had not to cut or bruise their roots. These plants, with this management, will continue several years, and will produce seeds in plenty.

If you would propagate these plants by offsets, their roots should be parted at Michaelmas, and planted in a shady situation, at the same distance as has been directed for the seedling plants, observing to water them until they have taken root, after which time they must be managed as the seedlings.

The roots of this plant are used in medicine, and are greatly recommended for their virtue in contagious distempers, or the bites of venomous creatures; they are alexipharmic and sudorific; by some they are recommended for cholics and asthmas, for the cramp, and all cold diseases of the nerves.

INARCHING is a method of grafting, which is commonly called grafting by approach. This method of grafting is used when the stock you intend to graft on, and the tree from which you would take the graft stand so near (or can be brought so near) that they may be joined together. The method of performing it is as follows: take the branch you would Inarch, and having fitted it to that part of the stock where you intend to join it, pare away the rind and wood on one side about three inches in length. After the same manner cut the stock or branch in the place where the graft is to be united, so that the rind of both may join equally together, at least on one side, that the sap may meet; then cut a little tongue upwards in the graft, and make a notch or slit in the stock downward to admit it; so that when they are joined, the tongues will prevent their slipping, and the graft will more closely unite with the stock. Having thus placed them exactly together, you must tie them with some bals, or other soft bandage; then cover the place with grafting clay, to prevent the air from entering to dry the wound, or the wet from getting in to rot the stock: you should also fix a stake into the ground to which that part of the stock, as also the graft should be fastened, to prevent the wind from breaking them asunder, which is often the case when this precaution is not observed.

In this manner they are to remain about four months, in which time they will be sufficiently united, and the graft may then be cut from the mother tree, observing to slope it off close to the stock; and if at this time you cover the joined parts with fresh grafting clay, it will be of great service to the graft.

This operation is always performed in April or May, that the graft may unite with the stock before the succeeding winter, and is commonly practised upon Oranges, Myrtles, Jasmines, Walnuts, Firs, Pines, and several other trees, which will not succeed so well by common grafting or budding. But although I have mentioned Orange-trees among the rest, yet I would by no means advise this practice where the trees are designed to grow large, which, in this method, they rarely ever will do; and it is chiefly practised upon those trees only as a curiosity, to have a young plant with fruit upon it, in a year or two from seed, by Inarching a bearing branch into a young stock, whereby it is effected, yet these plants are seldom long lived.

INDIGOFERA. Lin. Gen. 889. Indigo.

The CHARACTERS are,

The empalement is of one leaf, spreading almost flat, and cut into five segments; the flower is of the butterfly kind,

having a roundish spreading standard, which is indented at the point and reflexed: the wings are oblong, obtuse, and their under borders spreading; the keel is obtuse, spreading, and acute-pointed. It hath ten stamina digested in a cylinder whose points ascend, terminated by roundish summits, and a cylindrical germen, supporting a short style, crowned by an obtuse stigma. The germen afterward becomes a long taper pod, inclosing kidney-shaped seeds.

This genus of plants is ranged in the third section of Linnæus's seventeenth class, intitled Diadelphia Decandria, from the flowers having ten stamina formed in two bodies.

The SPECIES are,

1. **INDIGOFERA** (*Tindoria*) leguminibus arcuatis incanis, racemis folio brevioribus. Flor. Zeyl. 273. Indigo with hoary arched pods, and the bunches of flowers shorter than the leaves. April five Indigo Americana, filiquis in falculæ modum contortis. Acad. R. Scien. 1718. Guatimala Indigo.
2. **INDIGOFERA** (*Suffruticosa*) leguminibus arcuatis incanis, caule fruticosa. Indigo with a shrubby stalk, and hoary arched pods. Colutea affinis fruticosa argentea, floribus spicatis è viride purpureis, filiquis falcatis. Sloan. Cat. Jam. 142.
3. **INDIGOFERA** (*Caroliniana*) leguminibus teretibus, foliolis quinque spicis longissimis sparsis, radice perenne. Indigo with taper pods, leaves with five lobes, long loose spikes of flowers, and a perennial root.
4. **INDIGOFERA** (*Indica*) leguminibus pendulis lanatis compressis, foliis pinnatis. Indigo with woolly, compressed, hanging pods, and winged leaves.
5. **INDIGOFERA** (*Glabra*) leguminibus glabris teretibus, foliolis trifoliatis. Indigo with smooth taper pods, and trifoliate leaves.

The first and fifth sorts are annual plants with us; the seeds of these must be sown on a hot-bed early in the spring of the year, and when the plants are come up two inches high, they should be transplanted into small pots filled with good fresh earth, and the pots plunged into a hot-bed of tanners bark; when the plants have obtained some strength, they must have a great share of free air, by raising the glasses in the day time; and in June they may be exposed more to the open air, by which time they will begin to produce their flowers, which will be succeeded by pods in a short time after, and in August their seeds will be perfected, if the plants are brought forward in the spring.

The second sort grows to the height of five or six feet, and will abide two or three years, if it is preserved in a very warm stove in winter; this produces spikes of flowers from the wings of the leaves on the sides of the stems of the plant, and sometimes will perfect its seeds in England. This must be raised in a hot-bed, as was directed for the two former, but must not be wholly exposed to the open air, even in the hottest weather.

The fourth sort is supposed to be promiscuously used to make the Indigo, but the first is the common sort which is cultivated in the English plantations in America; but I have been assured by a person of great credit, that he has made as good Indigo from the second sort, as any that was produced in our plantations; and this being a much larger plant, will afford a greater quantity from the same compass of ground, than any one of the other species, especially if cut before the stalks grow ligneous; and this sort will grow on poorer land, so may be cultivated in such places where the first sort will not thrive so well, by which means great improvements may be made with this plant in our American plantations. There are some other sorts of this plant which are natives of India, from which this commodity is made; two of which, viz. the fourth and fifth sorts I have had growing in the garden at Chelsea, both which are very different in their leaves and pods from either of the American sorts which have been cultivated. I have also received seeds from India of the third sort, which is the same species of Indigo which grows naturally in South Carolina, and which was greatly esteemed

some years ago by the Indigo planters of that country, for the beauty of the commodity which it produced; but the plants being slender and thinly garnished with leaves, which were small, they did not furnish a quantity of Indigo in proportion to their bulk, so of late this sort has not been much cultivated there; though the account which I received with the seeds was, that it was what the best Indigo of India was made from.

The whole process in making the Indigo being exactly described by Pere Labat in his voyages, I thought it would not be unacceptable to the English reader, to translate his account in this place, which is as follows:

There was formerly a great deal of Indigo made in the parish of Macauba: there is not a stream nor river in it, where one does not meet with Indigo works, that is, backs or vats of stone-work well cemented, in which the plant that yields the dye is put to digest: there are usually three of these vats one above another, in the manner of a cascade; so that the second, which is lower than the bottom of the first, may receive the liquor contained in the first, when the holes which are made in the bottom of the first are unstopped; and that the third may in its turn receive what was in the second.

The first, largest, and highest of these vats is called the steeper or rot; it is usually made twenty feet long, twelve or fifteen feet wide, and three or four feet deep. The second is called the battery, it is almost half as small again as the first: and the third, which is much less than the second, is called the devilling.

The names of the two first perfectly agree with their uses, for the plant is laid to steep in the first, where it ferments, is macerated, and becomes like rotten dung: after that the salts and substance of the leaf and rind are diffused in the water by the fermentation, which the heat and ripeness of the plant has excited in it. It is in the second that they agitate and beat this water, impregnated and loaded with the salts of the plant, till having collected, re-united, and, as it were, coagulated them with one another, they form the particles which compose the dye.

As for the name of the third, I do not see how it agrees with it, unless it be because this vat is deeper coloured than the others; for the Indigo already formed remaining in it, consequently dyes and colours it much deeper than the others.

To which I should add, that it is only at St. Domingo that they make use of this name. In the Windward Islands they call this last vat the settler, and this name suits it perfectly well, because it is in this, that the Indigo begun in the steeper, and perfected in the battery unites, grows into a mass, separates itself from the particles of water which remained in it, leaves them at top, and settles at the bottom of the vat; whence it is taken out to be put into little bags, and then into the boxes, as I shall mention hereafter.

Nothing ought to be omitted in the building and making these vats substantial; the strength of the fermentation is so great, that unless the stone-work and plaster be very well done, and the mortar carefully chosen and wrought, they crack; and a very moderate crack is sufficient to let out a vat of Indigo, and cause a considerable loss to the owner.

When this misfortune happens, the following is an easy and infallible remedy, which I can answer for, as having experienced it. Take some sea shells of any kind whatever, pound them without burning them, powder them, and sift them through a fine sieve. Take an equal quantity of quick lime and sift it; mix these together with water enough to make a stiff mortar, and as quick as you can, stop the cracks of your vats with it. This mixture incorporates, sticks, and dries in a moment, and immediately prevents the matter's running out of the vat.

Every body does, or should know, that Indigo is a dye used to dye wool, silk, cloths, and stuffs, blue: the Spaniards call it Anilo: the finest they make, i. e. in New Spain, comes from Guatimala, which makes

a great many people call it barely Guatimala. It is made also in the East-Indies, particularly in the dominions of the Great Mogul, the kingdom of Golconda, and other places thereabouts, as Mr. Tavernier relates in his voyages. This sort is in Europe oftener called India than Indigo or Anil, people taking for its proper name the name of the place it was made at. Some authors, and among others, Father du Tertre of our order, having fancied that the Indigo which comes from the East-Indies is more beautiful, finer, and dearer, than that which comes from the West-Indies, which they call flat Indigo, while they call that from the East barely India. They would have spoken more properly, if they had called the latter round India; for, by their leave, all the difference between the two Indias, or Indigos, is, that that made in the East-Indies is shaped like half eggs, and that of the West like cakes; for as for goodness and beauty, the one will not be a whit superior to the other, if both are wrought with equal care and fidelity.

The shape of the Oriental Indigo obliges the merchants who would carry it into Europe to pound it, that they may put the more into the chests, or barrels they put it up in. It is certain, that being thus pounded, its grain having been broken under the pestle, ground, and reduced to powder, makes it finer than the West-Indian Indigo, which coming in cakes just as it was dried, shews its grain entire, and consequently must appear coarser; but what is that to the intrinsic goodness of the commodity; I maintain it is the same in both, though there seems to be a difference.

To be convinced of this truth, take a lump of sugar equally white throughout, break it in two, pound one part of it, and reduce it to powder; this will look finer and whiter than that which is whole, which proceeds only from this, that the grain of the one has been separated and divided into a greater number of parts, which, though very small, and almost insensible, yet have a greater number of surfaces, and consequently reflect more light; whereas the other remaining entire, presenting to the sight only a large grain, which has but little surface, of course reflects less light, and by a necessary consequence must appear less white; which is the same as appearing less beautiful, since the beauty of sugar consists in its whiteness. Methinks we may reason in the same manner upon Indigo, and say, that *cæteris paribus*, the West-Indian Indigo is as beautiful as the East-Indian, when they are both wrought alike.

I think I should add, that the American Indigo is better for use than the other; for who does not see, that there is no pounding this dye, without the most subtle parts being dissipated in the air, as Mr. Tavernier allows? And who can doubt that these parts are the best, and those that go farthest when it is used?

I grant that the Indigo which comes from the East-Indies, is dearer than that which is made in the West-Indies; the reason is plain, it comes farther, runs greater risks; and those who bring it would not find their account in selling it, at the same price with that which comes from a much nearer place; but that does not at all prove it to be more beautiful, or better.

Indigo is composed of the salt and substance of the leaves and rind of a plant of the same name; so that one may say, it is a dissolution or digestion of the plant, caused by the fermentation it has excited in the water it was laid to steep in. I know some writers pretend, that the substance of the leaves does not produce the Indigo, which (as they would have it) is only a viscous tincture, or colour, which the fermentation of the plant diffuses in the water: but before I take their words for it, I desire they would tell me what becomes of the substance of the plant; for when it is taken out of the steeper, it is certain, that it has no longer the same weight, consistence, nor colour, it had before. The leaves, which were very plump,

plump, and very full of juice; are light, flabby; and withered, and look more like dung than any thing else, which makes them frequently give the name of rot to the steeper. If then we no longer find in the leaves, and the rest of the plant, the same substance that was observable in it before it was laid to steep, is it not most natural to believe, that it is the same substance and salts, which, being freed from their inclosures, and diffused in the water, have thickened it, and by their union or coagulation have formed that blue mass which they call Indigo, so useful in painting and dyeing?

The culture.] This plant requires a good rich level soil, not too dry; it greatly robs and impoverishes the ground where it grows, and must be alone. There cannot be too much care taken to keep it clean, and to hinder herbs of any kind whatever from growing near it. They weed and cleanse the ground where they intend to plant the Indigo seed, five times over. I should think they should call it sowing, but the term of planting is consecrated in our isles, and I do not think I ought for the sake of a word to fall out with our planters, who deserve our esteem upon a thousand accounts, though they have got a habit of murdering the French language. They sometimes carry their neatness to such a pitch, that they sweep the piece of ground as they do a room. After that they make the holes wherein the seeds are to be put for this purpose; the slaves, or others, who are to work at it, range themselves in the same line, at the top of the piece of ground; and going backwards they make little drills the breadth of their hoe, of the depth of two or three inches, at about a foot distance every way, and as much as possible in a strait line. When they are come to the end of the ground, each furnishes himself with a little bag of seeds, and returning that way they came, they put eleven or thirteen seeds into each of the holes they have made. A relick of superstition has taught them that the number must be odd. I by no means approve of this practice, but I shall take care not to endeavour to shew them the uselessness and folly of it, being satisfied I shall only lose my time and labour.

This work is the most toilsome of any in the manufacture of Indigo; for those who plant it must be always stooping, without rising up, till the planting of the whole length of the piece is ended; so that when that is large, which almost always happens, they are obliged to remain two hours, and often more, in this posture.

When they come to the top of the piece, they go back again, and cover the holes where they have put the seed in, by thrusting in with their feet the earth they had taken out of them, and so the seed is covered with about two inches of earth.

The culture of this plant may be rendered very easy, provided the inhabitants of our colonies in America could be brought to make use of the drill plough; for with this instrument two persons and a horse or mule will sow more land with Indigo in one day, than twenty persons can perform in the same time, in the method now practised; for the plough makes the drill, and the hopper which is fixed to the plough follows, and scatters the seeds at equal distances in the drills; and another instrument behind the hopper covers in the drills, whereby the whole operation is performed at the same time, and with great ease. Indeed the use of this machine must be understood by the persons who are to perform it, otherwise they will do it in a bad manner, but a little practice will bring any person to the right use of it.

As the Indigo is sown in rows, a hoeing plough may be made of a proper dimension, in order to clean the ground between the rows; with this contrivance it may be performed in much less time than in the method now practised. But in doing of this, I would advise the stirring of the ground, soon after the Indigo plants are come up, before the weeds have got much strength, at which time they are soon destroyed; and by stirring of the ground the plants will be greatly

encouraged; and the strongest and most thriving plants will always make the best Indigo.

What Le Bat says of cutting the plants before they are too old, in order to have the Indigo of a better colour, is certainly right. Therefore as soon as the flowers begin to appear, it should be cut; for if it stands much longer the stems of the plants will grow hard and stringy, and the lower leaves will change to a yellowish colour, which will render the Indigo less valuable; as will also the plants being too close together, which will occasion their bottom leaves to decay for want of free air: the same will happen if weeds are suffered to grow among the plants. Therefore there must be great regard to their being kept always clean.

Though all seasons are good for the planting of Indigo, yet care must be taken not to put it in the ground in a dry time: it is true, the seed may keep a whole month in the ground, without being spoiled; but when it is planted so, one runs the risk of having it eaten up by vermin, or carried away by the wind, or choked by the weeds that spring up with it; so that the prudent planters never run the risk of planting it dry, i. e. at a time when they do not probably expect rain in two or three days after the planting is ended: they chuse therefore, usually, a moist season, which promises rain, and then they are sure of seeing the plant spring up in three or four days after its being planted.

Notwithstanding all the care that has been taken in clearing the ground where the seeds have been planted, the planter must not be careless when the Indigo is got above ground; because the goodness of the soil, joined to the moisture and warmth of the climate, and the plentiful dews that fall every night, makes a prodigious quantity of weeds spring up, which would choke and absolutely spoil the Indigo, if extreme care was not taken to weed them up as soon as they appear, and to keep the plant extraordinary neat; and very often the weeds are partly the cause of the breeding of a kind of caterpillars, which devour all the leaves in a short time.

From the time of the plants rising above ground, to its perfect maturity, is but two months, and then it is fit to cut: if one was to stay longer it would blossom, its leaves would grow drier and harder, and consequently they would yield less substance, and the colour would not be near so beautiful.

After this first cutting, the new branches and leaves which the plant produces may be cut about every six weeks, provided the season be rainy, and that care be taken not to cut it in a time of drought, because then we should infallibly lose the plant, or, as they call it there, the Choupues, and be obliged to plant again; but all things being rightly managed, the plant may last two years; after which it must be plucked up, and new ones planted.

When the plant is ripe, which is known by the leaves, which grow brittle and less supple, they cut it some inches from the ground. They use for the cutting of it great crooked knives made like sickles. Some planters make it into bundles like double bottles of hay, that a negro may easily carry them to the steeper; but most people put it into large pieces of coarse cloth, which they tie by the four corners; and this is more convenient, the plant is less handled and squeezed, and the small are carried away as safely as the great; and besides the work goes on quicker this way, than in making bottles; and as time is precious every where, and especially in America, there cannot be too much care taken not to lose any.

Eighteen or twenty packets of plants, each about the size of two bottles of hay, are sufficient to fill a steeper of the afore-mentioned size. When it is filled with water, so that it covers the plants, they put pieces of wood on the top, that the plants may not rise above the water (much after the manner as they do upon the Grapes that are put into the press) and let all ferment. According as the heat is greater or less, or the plant more or less ripe, the fermentation is raised sooner or later,

later, sometimes in six, eight, or ten hours; and sometimes one is obliged to wait eighteen or twenty hours, but very seldom longer. Then the effect of the fermentation visibly appears, the water heats, and boils up on all sides, as the Grapes do in the vat; and the water which at first was clear, insensibly grows thick, and becomes of a blue, inclining to a Violet colour. Then without meddling at all with the plants, they open the cocks, which are at the bottom of the steeper, and let all this water, loaded with the salts and substance of the plant, which were freed by the fermentation, run into the battery; and while they throw away as useless, and almost rotten, the plants that were in the steeper, and clean it, that it may be filled with fresh, they beat the water, which they have let out of the steeper into the battery.

They formerly used for this purpose a battledoor wheel, whose axle was placed upon the middle of the vat, and which they turned by two handles that were at the end of the same axle. Since that, in the room of battledoors, they have put little bottomless boxes, and afterwards others, whose bottoms were bored full of holes: at present they use a kind of pretty large pails, fastened to strong poles, placed upon chandeliers, by means of which, the negroes violently and continually raise, beat, and stir the water, till the salts and other parts of the substance of the plant are united, and sufficiently, as it were, coagulated to incorporate.

The hitting this minute exactly shews the skill of him who oversees the making of the Indigo; for if he makes them leave off beating a little too soon, the grain not yet formed, remains dispersed in the water, without sinking and gathering together at the bottom of the vat, and is lost with the water, when they are obliged to let it out, which is a great loss to the owner; or if when it is formed they continue to beat, they dissolve it, and the same inconvenience follows. This minute then must be nicked, and when it is found, they must leave off beating and let the matter rest.

To find this minute, they make use of a little silver cup, designed for this use alone; they fill it with this water, while the negroes beat it, and according as they observe that the faeces sink to the bottom of the cup, or remain dispersed in the water, they cease, or continue beating.

The General Dictionary printed at Trevoux, relates very seriously, upon the credit of father Plumier a minim, that the Indigo-maker having taking up some of the water of this battery in his cup, spits it in; and that if the Indigo be formed, the faeces immediately sink to the bottom of the cup, and that then he makes them leave off beating, if not, he makes them continue it. This is not the only incident in which people have imposed upon father Plumier's credulity and simplicity. I have been a witness of it upon other occasions.

When they have left off beating they let the matter rest, the faeces sink to the bottom of the vat, and gather together like a kind of mud; and the water freed from all the salts it was impregnated with, swims above it, and grows clear. Then they open the cocks, which are placed in the battery at different distances from the bottom, and let this water run away; and when they come to the surface of the faeces, they open the cocks of the bottom, that the faeces may all fall into the devilling or settler. There they let it settle a little while longer, after which they put it into linen bags, fifteen or eighteen inches long, made with a point, where it perfectly purges itself from the rest of the water, which remained among its particles. When that is done, they spread it in little boxes three or four feet long, two feet broad, and about three inches deep; and expose it to the air to dry it perfectly. They observe not to expose it to the sun, because it would starve the colour in drying it; and they take a great deal of care to keep it from the rain, because that would dissolve and utterly spoil it.

It sometimes happens that the caterpillars get among the Indigo; and if they are let alone ever so little a while they eat all the leaves, and often the very rind and ends of the branches, and kill the stocks; it is but lost time to endeavour to destroy them, or hinder them from ravaging a whole piece, by stopping them with a ditch. The surest way is to cut down the Indigo with all speed, let its age be what it will, and to throw both plants and caterpillars together into the steeper; there they burst, and part with what they had devoured, and the Indigo is not the less beautiful for it. It is true, when the plant is not come to its perfect maturity, it yields much less; but many experiments have taught us, that the colour it yields is much more beautiful; so that what is lost one way is gained another.

I would not wait for so perfect a ripeness before I cut the plant. Perhaps all the secret of those, whose Indigo is so much extolled beyond ours, lies only in cutting the plant when it yields the liveliest colour. I have experienced that in leaving some cochineal flies upon some Indian Figs, which were too ripe, instead of being red, they grew of a filemot colour, like the fruit they fed upon. The same thing might happen in Indigo; and what I here propose is not a groundless doubt, since it is backed by the experiment I have just related; which plainly proves, that the same plant, cut at different ages, produces colours different in beauty. I would not venture to give this advice to men wedded to their interest, who value the quantity rather than the quality of their commodity; but I believe I have nothing to fear from our islanders, who are generous and magnificent, sometimes even beyond their abilities: I advise them therefore to make different trials, as to the soil, the season, the age of the plant, the water they steep it in, the point of dissolution, &c. and I am sure, that with a little time, labour, and patience, they will make Indigo that will equal, and even excel, the most boasted Indigo of foreign countries. The planters of St. Domingo know that in 1701 their coarse sugar was very bad, and was not made without infinite trouble; and at present every body allows, that by their labour, assiduity, and enquiries, it is grown much more esteemed than that of the Windward Islands: why may not the same be hoped for in Indigo?

Mr. Pomet, author of the General History of Drugs, says in his first part, chap. 10. That the Indians of the village of Sarquesse, near Amadabat, use only the leaves of the Indigo, and throw away the plant and branches; and that it is from thence the most esteemed Indigo comes.

I am pretty much of his opinion; for we see, that those who take the pains to strip off the Grapes from the branches, before they put them into the vat, and throw away the stalks entirely, make much the best wine; because the stalks always contain an acid, which mixes with the juice of the Grape in the treading and pressing them both together; and for the same reason, the stalks of the Indigo plant must contain a liquid much less perfect in colour than that of the leaves: but one ought to have the leisure and patience of the Indians to undertake such a work, and have workmen as cheap as they are in that country, supposing the fact true, as Mr. Pomet delivers it from the relation of Mr. Tavernier.

Though I am a great friend to those experiments which may carry our manufactures to a greater perfection, yet I dare not propose this, because of the expence they must be at, who would try it; and because the profit arising from it would not perhaps quit cost: however, I have here given the method of the Indians of Sarquesse, that I may have no reason to reproach myself with having omitted a thing which may be of some use to my country.

Good Indigo ought to be so light, as to swim upon water; the more it sinks the more it is to be suspected of being mixed with earth, ashes, or powdered slate. Its colour ought to be a deep blue, inclining to a Violet, brilliant, lively, and bright: it ought to be more

more beautiful within than without, and look shining, and as it were silvered.

If it is too heavy in proportion to its bulk, it ought to be suspected, and its quality examined into; for as it often bears a considerable price, it is fit that those who buy it, should be acquainted with the frauds that may be committed in it.

The first is the beating the plant too much in the steeper, that the leaves and rind of it may be entirely consumed. It is certain that the quantity of the matter is very considerably increased by this dissolution, but the Indigo is a great deal the less beautiful for it; it is blackish, thick, heavy, and fitter to be thrown away than used.

The second is the mixing ashes, earth, or a certain brown shining sand (which is pretty commonly found in the bays by the sea-side) and especially powdered slate, with the fæces, as they fall into the devilling, and stirring all well together, that it may incorporate, and the fraud not appear: and this fraud is much more easily committed in the powdered Indigo, than in that which is in cakes; because it is very difficult for those heterogeneous bodies to unite so well together, as not to make in many places, as it were, beds of a different matter; and then, by breaking the piece of Indigo, they are easily perceived.

The two following expedients may be made use of, in order to know the goodness or badness of Indigo.

The first is to dissolve a bit of it in a glass of water. If it is pure and well made, it will entirely dissolve; but if it is adulterated, the foreign matter will sink to the bottom of the glass.

The second is to burn it. The good Indigo will burn all away, whereas the ashes, earth, sand, and slate, remain after the true Indigo is consumed.

In 1694, Indigo was sold at the Windward Islands, from three livres ten sols, to four livres per pound, according to its beauty, and the number of vessels to be freighted with it. I have known it since at a much lower price; however, the planter would not fail of making a very considerable profit of it, though he should sell it for no more than forty sols per pound, because this commodity requires fewer utensils and less charges than a sugar-work.

Since the cultivation of Indigo was introduced in South Carolina, great quantities of that useful dye has been brought from thence to England; and it may be hoped that the encouragement granted by parliament to the planters, will enable them to prosecute this branch of commerce with such success, as to be a great national benefit, and of equal advantage to that colony: but as yet the planters have not arrived to so much perfection in the making of it as could be wished; for most of the Indigo which I have seen of the produce of that country, has been so hard as to render it difficult to dissolve, occasioned by their pouring a quantity of lime-water into the vat, in order to make the fæces of the plant subside. I have also been informed by letters from many of the planters, that after the fermentation of the plant in the vat, it comes out again almost entire, being but in a very small proportion lessened, either in bulk or weight. This may probably be owing, in great part, to their culture of the plant, as also from their vats not being large enough to contain a sufficient quantity of the herb, to make the fermentation strong enough to dissolve it; or from the vats being built in the open air, whereby the fermentation may be impeded, by the cooler breezes of the evening air: for in the islands where the best Indigo is made, their vats are all built under cover, where their heat is much greater than that in Carolina, therefore this requires the attention of the planters of Indigo.

As to the culture of the plant, by all the information I have been able to procure from thence, they commit a great error in sowing their seeds too thick, whereby the plants are drawn up with slender stems, which are not sufficiently garnished with leaves; nor are the leaves so large and succulent as they would naturally

grow, were the plants allowed a greater share of room; so that the stalks consist of little else but strong vessels, which are not dissolvable by the fermentation, and it is only the upper parts of the plant which are furnished with leaves, like young trees growing close together which are drawn up with slender stems, having no lateral branches, nor leaves, but at their tops; therefore it is not to be supposed, a great quantity of Indigo can be produced from plants so managed; for it is a common observation of the cultivators of Woad, that when their plants spire, and have narrow thin leaves, they produce but little of the dye; so that they make choice of rich strong land for sowing the seeds of this plant, and are careful to thin them; that they may have room to spread, and produce large succulent leaves, from which they always reap the greatest profit. If the planters of Indigo in America would but imitate the cultivators of Woad in this particular, they would certainly find their advantage in so doing.

Another thing in which they err is, letting the plant stand too long before they cut it, supposing from the height of the plant to procure a great quantity of the dye; but in this they are greatly mistaken, for the older the plant is before it is cut, the drier and firmer will be the stalks; therefore but little of the plant will be dissolved by fermentation, nor will the fæces of the old plants be near so beautiful as that of the young. Therefore it is to be wished, that they would try some few experiments in the culture and management of the plants, by sowing thin, and keeping the plants perfectly clean from weeds; as also to cut them while young and full of juice, and hereby they will be better informed how to improve it to the greatest advantage. But as labour is dear in that country, so many persons probably object to the expence of cultivating the Indigo in this method; therefore, to avoid this, I have before proposed sowing the seeds with a drill plough, whereby the first expence will be greatly lessened, and the seeds more equally sown; and by the use of the hoe plough, ten acres may be kept clean from weeds with as small expence, as one when managed by the hand hoe; and by stirring of the ground often, and earthing up the plants, they would grow much stronger, be less liable of being destroyed by flies, and have larger and more succulent stalks and leaves.

INGA. See MIMOSA.

INOCULATING, or Budding. This is commonly practised upon all sorts of stone fruit, in particular, such as Peaches, Nectarines, Cherries, Plums, &c. as also Oranges and Jasmines, and is preferable to any sort of grafting for most sorts of fruit. The method of performing it is as follows: you must be provided with a sharp penknife, having a flat haft (the use of which is to raise the bark of the stock, to admit the bud) and some sound bass mat, which should be soaked in water to increase its strength, and make it more pliable; then having taken off the cuttings from the trees you would propagate, you should choose a smooth part of the stock about five or six inches above the surface of the ground, if designed for dwarfs, and for half standards at three feet; but for standards, they should be budded six or more feet above ground; then with your knife make an horizontal cut cross the rind of the stock, and from the middle of that cut make a slit downwards about two inches in length, so that it may be in the form of a T; but you must be careful not to cut too deep, lest you wound the stock: then having cut off the leaf from the bud, leaving the foot-stalk remaining, you should make a cross cut about half an inch below the eye, and with your knife slit off the bud, with part of the wood to it, in form of an escutcheon: this done, you must with your knife pull off that part of the wood which was taken with the bud, observing whether the eye of the bud be left to it, or not (for all those buds which lose their eyes in stripping, should be thrown away, being good for nothing) then having gently raised the bark of the stock where the cross in-

cision was made, with the flat haft of your penknife clear to the wood, you should thrust the bud therein, observing to place it smooth between the rind and the wood of the stock, cutting off any part of the rind belonging to the bud, which may be too long for the slit made in the stock; and so having exactly fitted the bud to the stock, you must tie them closely round with bals mat, beginning at the under part of the slit, and so proceed to the top, taking care that you do not bind round the eye of the bud, which should be left open.

When your buds have been inoculated three weeks or a month, you will see which of them have taken; those of them which appear shrivelled and black, being dead, but those which remain fresh and plump, you may depend are joined; and at this time you should loosen the bandage, which, if not done in time, will pinch the stock, and greatly injure, if not destroy, the bud.

The March following you must cut off the stock about three inches above the bud, sloping it that the wet may pass off, and not enter the stock; to this part of the stock left above the bud, it is very proper to fasten the shoot which proceeds from the bud, and would be in danger of being blown out, if not prevented; but this must continue no longer than one year, after which it must be cut off close above the bud, that the stock may be covered thereby.

The time for Inoculating is, from the middle of June until the middle of August, according to the forwardness of the season, and the particular sorts of trees to be propagated; but the time may be easily known, by trying the buds, whether they will come off well from the wood. However, the most general rule is, when you observe the buds formed at the extremity of the same year's shoots, which is a sign of their having finished their spring growth. The first sort commonly inoculated is the Apricot, and the last the Orange-tree, which should never be done until the middle of August; and in doing of this work, you should always make choice of cloudy weather; for if it be done in the middle of the day, in very hot weather, the shoots will perspire so fast, as to leave the buds destitute of moisture; nor should you take off the cuttings from the trees long before they are used; but if you are obliged to fetch your cuttings from some distance, as it often happens, you should then be provided with a tin box or case, having a socket about ten inches long, and a cover to the top, which must have five or six holes; in this socket you should put as much water as will fill it about two or three inches high, and place your cuttings therein in an upright position, so that that part which was cut from the tree may be set in the water, and so fasten down the cover to keep out the air; and the holes in the cover will be sufficient to let the perspiration of these branches pass off, which, if pent in, would be very hurtful to them; you must also be careful to carry it upright, that the water may not reach to the buds; for it is a very wrong practice in those who throw their cuttings all over in water, which so saturates the buds with moisture, that they have no attractive force left to imbibe the sap of the stock, whereby they very often miscarry.

But before I leave this head, I beg leave to observe, that though it is the ordinary practice to divest the bud of that part of the wood which was taken from the shoot with it; yet, in many sorts of tender trees, it is best to preserve a little wood to the bud, without which they often miscarry. The not observing this, has occasioned some people to imagine, that some sorts of trees are not to be propagated by Inoculation; whereas, if they had performed it in this method, they might have succeeded, as I have several times experienced.

INTYBUS. See CICHORIUM.

INULA. Lin. Gen. Plant. 860. Enula. Cæsalp. Helenium. Raii Meth. 33. After. Tourn. Inst. R. H. 481. tab. 274. Elecampane.

The CHARACTERS are,

It hath a radiated compound flower, with an imbricated empalement, composed of loose, spreading, small leaves, the outer being the broadest. The disk, or middle of the flower, is composed of hermaphrodite florets, and the border, or ray of the female half florets, stretched out like a tongue. The hermaphrodite florets are funnel-shaped, erect, and cut into five segments at the top; these have five short slender stamina, terminated by cylindrical summits, which coalesce at the top: they have one long germen, crowned with down, supporting a slender style the length of the stamina, crowned by an upright bifid stigma. The female half florets have a narrow entire tongue, no stamina, but a long crowned germen with a hairy style, and an upright stigma. The germen in both flowers become a single, narrow, four-cornered seed, crowned with a down, sitting on a naked receptacle.

This genus of plants is ranged in the second section of Linnæus's nineteenth class, intitled Syngenesia Polygamia superflua, which includes the plants with a compound flower, made up of hermaphrodite florets in the disk, and female half florets for the rays, which are fruitful.

The SPECIES are,

1. INULA (*Helenium*) foliis amplexicaulibus ovatis, rugosis, subtus tomentosis, calycum squamis ovatis. Amœn. Acad. 1. p. 410. *Elecampane with oval rough leaves, which embrace the stalks, woolly on their under side, and the scales of the empalement oval. After omnium maximus, Helenium dictus. Tourn. Inst. 483. The greatest Starwort, called Elecampane.*
2. INULA (*Odora*) foliis amplexicaulibus dentatis hirsutissimis radicalibus ovatis, caulibus lanceolatis caule paucifloro. Lin. Sp. Plant. 1236. *Inula with hairy indented leaves embracing the stalks, those at the bottom oval, but those on the stalks spear-shaped, which have but few flowers. After luteus radice odora. C. B. P. 266. Yellow Starwort with a sweet root.*
3. INULA (*Salicina*) foliis sessilibus lanceolatis recurvis ferrato-scabris, floribus inferioribus altioribus, ramis sub-angulatis. Amœn. Acad. 1. p. 410. *Inula with spear-shaped, recurved, rough, sawed leaves, sitting close to the stalks, and the under flowers growing taller than the upper, and angular branches. After montanus luteus, salicis glabro folio. C. B. P. 266. Yellow Mountain Starwort with a smooth Willow leaf.*
4. INULA (*Germanica*) foliis sessilibus lanceolatis recurvis, scabris, floribus subs fasciculatis. Lin. Sp. Plant. 883. *Inula with spear-shaped recurved leaves sitting close to the stalks, which are rough, and flowers growing in clusters. After Thuringiacus altissimus latifolius, montanus, flore luteo parvo. Haller. Jen. 181. Tallest broad-leaved Mountain Starwort of Thuringia, with a small yellow flower.*
5. INULA (*Crithmoides*) foliis linearibus carnosissimis tricuspidatis. Lin. Sp. Plant. 883. *Inula with narrow fleshy leaves ending in three points. After maritimus flavus crithmum chrysanthemum dictus. Raii Syn. Ed. 3. p. 174. Yellow maritime Starwort, called Golden Samphire.*
6. INULA (*Montana*) foliis lanceolatis hirsutis integerrimis, caule unifloro calyce brevi imbricato. Lin. Sp. Plant. 124. *Inula with hairy, spear-shaped, entire leaves, one flower on a stalk, having a short scaly cup. After montanus luteo magno flore. C. B. P. 267. Mountain Starwort with a large yellow flower.*
7. INULA (*Oculis Christi*) foliis amplexicaulibus oblongis, integerrimis hirsutis, caule piloso, corymboso. Lin. Sp. Plant. 1237. *Inula with oblong, entire, hairy leaves, and flowers growing in a corymbus. Conyza Pannonica lanuginosa. C. B. P. 265. Hungarian woolly Fleabane.*
8. INULA (*Britannica*) foliis amplexicaulibus lanceolatis, distinctis ferratis, subtus villosis, caule ramoso villosa erecto. Flor. Suec. 756. *Inula with spear-shaped sawed leaves embracing the stalk, hairy on their under side, and an erect branching stalk. After palustris luteus, folio longiore lanuginoso. Tourn. Inst. 483. Yellow Marsh Starwort with a longer woolly leaf.*

9. INULA

9. *INULA (Hirta)* foliis sessilibus lanceolatis, recurvatis, subserrato-scabris, floribus inferioribus, altioribus, caule teretiusculo subpiloso. Lin. Sp. 1239. *Inula with spear-shaped, recurved, rough leaves, sitting close to the stalks, and the lower flowers rising above the other. After luteus, foliis hirsuto. C. B. P. 266. Yellow After with a hairy Willow leaf.*

10. *INULA (Bifrons)* foliis oblongis decurrentibus denticulatis, floribus congestis terminalibus subsessilibus. Lin. Sp. 1236. *Inula with oblong indented leaves running along the stalks, and flowers in clusters terminating the stalks. Conyza Pyrenaica, foliis primulae veris. Par. Bat. 127.*

11. *INULA (Squarosa)* foliis ovalibus laevibus reticulato-venosis subcrenatis, calycibus squarrosis. Lin. Sp. 1240. *Inula with smooth oval leaves and netted veins, with rough empalements to the flowers. After Conyzoides odoratus luteus. Tourn. Inst. 483.*

12. *INULA (Canariensis)* foliis linearibus carnosissimis tricuspidatis, caule fruticoso. *Inula with narrow, fleshy, three-pointed leaves, and a shrubby stalk. After Canariensis frutescens, folio tridentato crassa. Hort. Chelf. 26. Shrubby Canary Starwort with a thick leaf, ending in three points.*

13. *INULA (Saturejoides)* foliis linearibus hirsutis oppositis, pedunculatis nudis unifloris. *Inula with narrow hairy stalks placed opposite, and naked foot-stalks, having one flower. After Satureja foliis conjugatis & pilosis, flore luteo. Houst. MSS. Starwort with hairy Savoury leaves growing by pairs, and a yellow flower.*

14. *INULA (Mariana)* caule erecto hispido, foliis lanceolatis asperis, floribus alaribus solitariis sessilibus, terminalibus umbellatis. *Inula with an erect prickly stalk, spear-shaped rough leaves, flowers proceeding singly from the sides of the stalks, sitting close, and terminating in an umbel. After luteus Marianus Saligneis brevioribus foliis hirsutis pubescentibus, summo caule ramosus. Pluk. Mant. 30. Yellow Starwort of Maryland, with shorter, fallow, hairy leaves, and the top of the stalk branching.*

15. *INULA (Fruticosa)* foliis lanceolatis acutis, subtus trinerviis, squamis calycinis acutis caule fruticosa. *Inula with spear-shaped acute leaves, having three veins on their under side, the scales of the empalement sharp-pointed, and a shrubby stalk.*

The first sort grows naturally in several parts of England, but it is also cultivated in gardens for the sake of the roots, which are used in medicine, and are accounted carminative, sudorific, and alexipharmic, of great service in shortness of breath, coughs, stuffing of the lungs, and infectious distempers.

This hath a perennial root, which is thick, branching, and of a strong odour. The lower leaves are a foot long, and four inches broad in the middle, rough on their upper side, but downy on their under. The stalks rise about three feet high, and divide toward the top into several smaller branches, garnished with oblong oval leaves, which are indented on their edges, and end in acute points. The flowers terminate the stalks, each branch ending with one large, yellow, radiated flower, sitting in a scaly empalement, whose scales are oval, and placed like the scales on fish over each other. The flowers are succeeded by narrow four-cornered seeds crowned with down. It flowers in June and July, and the seeds ripen the latter end of August.

This sort may be propagated by seeds, which should be sown in autumn soon after they are ripe; for if they are kept till the spring, they seldom grow; but where they are permitted to scatter, the plants will come up the following spring without any care, and may be either transplanted the following autumn; or if they are designed to remain, they should be hoed out to the distance of ten inches, or a foot each way, and constantly kept clean from weeds; these roots will be fit for use the second year.

But most people propagate the plant by offsets, which, if carefully taken from the old roots, with a bud, or eye, to each, will take root very easily; the best time for this is the autumn, as soon as the leaves begin to

decay; these should be planted in rows about a foot asunder, and nine or ten inches distance in the rows; the spring following the ground must be kept clean from weeds, and if in autumn it is slightly dug, it will promote the growth of the roots; these will be fit for use after two years growth, but the roots will abide many years, if they are permitted to stand; however, the young roots are preferable to those which are old and stringy. It loves a gentle loamy soil, not too dry.

The second sort hath a perennial root, from which arise several stalks, about two feet high. The leaves at bottom are oval, indented, and hairy; those above embrace the stalks with their base. The stalks are divided into several branches, garnished with a few scattering yellow flowers. The root has a very sweet odour when broken. It flowers in July, but rarely ripens seeds here.

The third sort hath a perennial root, from which arises many spear-shaped leaves, which are smooth and recurved. The stalks rise near two feet high; they are angular, and branch at the top into several foot-stalks, each sustaining one yellow radiated flower. It flowers in June, July, and August, and the seeds ripen in September.

The fourth sort rises with an upright stalk between three and four feet high, with spear-shaped leaves, which are turned backward, indented on their edges, and rough on their upper side. The flowers are collected in close bunches on the upper part of the stalks; they are small and yellow. It grows on the Alps, and other mountainous parts of Europe. It flowers in June, and the seeds ripen in autumn.

The fifth sort grows naturally on the sea-coasts in many parts of England. I have seen it growing plentifully near Sheerness, in the isle of Sheepy, in Kent; this rises with an upright stalk a foot and a half high, garnished with fleshy succulent leaves, which come out in clusters, and are about an inch and a quarter long, and one eighth of an inch broad, ending in three points. The flowers come out at the top of the stalks in small umbels; they are yellow, and have a border of rays; this flowers in July, and the seeds ripen in autumn. The younger branches of this plant are frequently sold in the London markets for Samphire; but this is a great abuse, because this plant has none of the warm aromatic taste of the true Samphire.

The sixth sort grows naturally in Germany; this rises with upright stalks a foot and a half high, garnished with spear-shaped leaves which are covered with soft hairs, and are entire. The stalks each support one large yellow flower, which appears in July, but rarely ripens seeds here.

The seventh sort hath a perennial root and an annual stalk; this grows naturally in Hungary. The leaves are oblong and hairy; the stalks branch at the top in form of a corymbus. The flowers are small, yellow, and are in close clusters; these appear in July, but seldom perfect seeds in England.

The eighth sort grows naturally in Austria, Bohemia, and other parts of Germany; it hath a perennial root, and an annual stalk which rises near two feet high, garnished with spear-shaped woolly leaves, which are sawed, and closely embrace the stalks with their base. The upper part of the stalk divides into two or three erect branches, or foot-stalks, each sustaining one pretty large deep yellow flower; these are in beauty in July, but seldom ripen seeds here.

The ninth sort grows naturally in the south of France, Spain, and Italy; this hath a perennial root, from whence arise several stalks about one foot high; the lower leaves are spear-shaped and prickly; the upper half embrace the stalks, which divide into several branches, each being terminated by one yellow flower, which appears in July, but seldom perfects seeds here.

The tenth sort rises about a foot high, dividing into many branches, which are garnished by oval hairy leaves, which half embrace the stalks with their base; each

each of the branches is terminated by one large yellow flower, whose empalement is composed of oval scales. It flowers in July and August, but never perfects seeds in this country.

The eleventh sort grows naturally in Hungary; this rises with single upright stalks near two feet high, garnished with oval spear-shaped leaves, which are slightly indented on the edges, and sit close to the stalks, which are hairy, and divide in form of a corymbus at the top. The flowers are pretty large, of a pale yellow colour, and appear in July, but are not succeeded by seeds in this country.

The twelfth sort grows naturally in the Canary Islands; this rises with several shrubby stalks near four feet high, which divide into smaller branches, garnished with clusters of narrow fleshy leaves, which are divided into three segments at their points. The flowers come out on the side of the branches at the top of the stalks; they are small, and of a pale yellow colour, appearing in August.

The second, third, fourth, sixth, seventh, eighth, and ninth sorts are abiding plants, which will thrive and flower in the open air in England; they may be all propagated by parting of their roots. The best time for doing of this is in autumn, at which time the plants may be removed; these may be intermixed with other flowering plants in the borders of large gardens, where they will make an agreeable variety during their continuance in flower. As these roots multiply pretty fast, they should be allowed room to spread, therefore should not be planted nearer than two feet from other plants; and if they are removed every third year, it will be often enough, provided the ground between them is dug every winter, and, in summer, if they are kept clean from weeds, they will require no other care.

As some of these sorts produce good seeds in England, they may be propagated by sowing of the seeds in the autumn, on a border of light earth exposed to the east, where the morning sun only is admitted; and in the spring, when the plants appear, they should be kept clean from weeds till they are fit to remove, when they should be transplanted on a shady border, six inches asunder, observing to shade and water them till they have taken new root; and during the summer season they should be kept clean from weeds, and in autumn they may be transplanted into the borders where they are to remain.

The tenth sort grows naturally in the south of France, and on the Pyrenean mountains. This hath a thick fibrous root, which is perennial, sending out many oblong indented leaves, whose base runs along the stalks from one joint to another: from the root arise three or four stalks about two feet high, which divide each into three or four small branches, which are terminated by clusters of small yellow flowers, sitting close between the small leaves; these appear in June and July, and are succeeded by narrow seeds, crowned with down, which ripen in the autumn.

It is propagated by seeds, which should be sown on a bed of light earth early in the spring; in May the plants will appear, which should be kept clean from weeds till they are fit to transplant, when they should be planted in an east border, at about six inches distance each way, watering and shading them till they have taken new root; after which they will require no other culture but to keep them clean from weeds till the autumn, when they should be planted where they are designed to remain.

The eleventh sort grows naturally near Montpellier, and also in Italy; this hath a fibrous root, from which arise two or three erect stalks about two feet high, garnished with smooth oval leaves placed alternate, sitting close to the stalks; the veins of the leaves are slender, and formed like net-work. The stalks are terminated by one yellow flower inclosed in a rough scaly empalement, and at the two joints of the stalk immediately under the flower, come out small foot-stalks, with smaller flowers than those on the top.

This plant seldom continues above two or three years,

therefore young plants should be raised from seeds to succeed them. The seeds may be sown at the same time, and in the same manner as is directed for the tenth sort, and the plants afterward treated in the same way. The fifth sort grows naturally in the salt marshes in several parts of England, which are flowed by the tides, therefore is seldom admitted into gardens. The roots of this are perennial, but the stalks decay in autumn; and if any one has curiosity to keep a plant or two of it in their gardens, they may transplant it into a shady border from the place of its natural growth, and, by keeping it moist in dry weather, it will thrive pretty well, but the stalks will not rise so high, nor will the leaves be near so fleshy as in the salt marshes.

The twelfth sort will not live abroad in the open air in England, during the winter season, so must be removed into shelter in autumn, but should have as much free air as possible at all times, when the weather is mild, otherwise it is apt to draw up weak. In cold weather the plants must have very little water, for their stalks and leaves being succulent, they are very apt to rot with too much wet; in summer they should be placed abroad with other hardy exotic plants in a sheltered situation, where they will add to the variety, though they are plants of no great beauty, and seldom flower in England, unless the summer is very warm. This is easily propagated by cuttings, any time in summer, which, if planted in a shady border, will take root in a short time.

The thirteenth sort was discovered by the late Dr. Houstoun, growing naturally at La Vera Cruz; this rises with a shrubby stalk about two feet high, dividing into many smaller branches, which are hairy, and garnished with narrow stiff leaves placed opposite, without foot-stalks; from the edges of these arise long hairs, which are stiff, and come out by pairs; at the end of the branches arise the naked foot-stalks, which are four or five inches long, sustaining one small, yellow, radiated flower.

This is propagated by cuttings during the summer season, which must be planted on a bed of light earth, and shaded till they have taken root; after which the plants must be treated in the same manner as other hardy exotics, sheltering them from frost in winter.

The fourteenth sort was sent me from Maryland, where it grows naturally; this rises with a strong stalk about a foot and a half high, which is pretty closely set with prickly hairs, and garnished with rough spear-shaped leaves, about three inches long, and near one inch broad in the middle: toward the upper part of the stalk there are single flowers coming from the wings at each joint, and the stalk is terminated by a cluster of small yellow flowers, disposed in form of an umbel. This plant flowers here in August, but has not as yet perfected seeds in England.

The fifteenth sort was discovered growing naturally at Carthage, by the late Dr. Houstoun; this rises with a shrubby stalk to the height of ten or twelve feet, divided into several ligneous branches, garnished with spear-shaped leaves five inches long, and one inch and a half broad in the middle, and smooth on their upper side, but on their under have three longitudinal veins. The flowers are produced at the end of the branches, having very large scaly empalements; they are as large as a small Sun-flower, of a pale yellow colour. This plant is too tender to live in the open air in England, so must be constantly kept in the bark-stove. It is propagated by seeds, which must be procured from the country where it naturally grows, for it does not produce any here; these must be sown upon a hot-bed, and when the plants are fit to remove, they should be each planted into a small pot filled with light earth, and plunged into a fresh hot-bed, treating them in the same manner as other tender plants from the same country.

JOHNSONIA. Dale. Callicarpa. Lin. Gen. Plant. 127. Spondylococus. Mitch. 20. This plant was so titled by the late Dr. Dale, of South Carolina, in memory of Dr. Johnson, who published an edition of Gerard's Herbal, corrected and much improved.

The CHARACTERS are,

The flower hath an empalement of one leaf, cut at the brim into four short segments, which are erect. It hath one petal, which is tubulous, and divided into four parts at the brim, which spread open. It hath four slender summits, which are longer than the petal, terminated by oblong yellow summits. In the center is situated a roundish germen, supporting a slender style, crowned by a thick obtuse stigma. The germen afterward becomes a smooth globular berry, inclosing four hard oblong seeds.

Dr. Linnæus ranges this genus of plants in the first section of his fourth class, intitled Tetrandria Monogynia, which includes the plants whose flowers have four stamina and one style. As the seeds of this plant were sent me from Carolina by the late Dr. Dale with this title, in the year 1739, and with them the characters of the genus, which was before it was mentioned by Dr. Linnæus, I have continued it under the Doctor's title.

We have but one SPECIES of this genus, viz.

JOHNSONIA (*Americana*) floribus verticillatis sessilibus, foliis ovato lanceolatis oppositis, caule fruticoso. Dale. *Shrubby Johnsonia with oval spear-shaped leaves placed opposite, and flowers growing in whorls sitting close to the stalks.* Callicarpa. Act. Upsal. 1741. Mr. Catesby, in his History of Carolina, has figured it under the following title, Frutex baccifer verticillatus, foliis scabris latis dentatis & conjugatis, baccis purpureis dense congestis, vol. ii. p. 47.

This shrub grows plentifully in the woods near Charles-town, in South Carolina. It rises from four to six feet high, sending out many branches from the root, which are woolly when young, like those of the Wayfaring-tree, garnished with oval spear-shaped leaves placed opposite, standing on short foot-stalks; they are about three inches long, and one inch and a quarter broad in the middle, growing narrow at both ends, and a little indented on their edges, their surface rough, and a little hoary. The flowers come out in whorls round the stalks, sitting very close to the branches at the foot-stalks of the leaves; they are small, tubulous, cut into four obtuse segments at the top, which expand, and are of a deep purple colour; these are succeeded by soft succulent berries, which turn first to a bright red colour, but afterward change to a deep purple when ripe, and inclose four hard oblong seeds.

The seeds of this plant were sent me by Mr. Catesby, from Carolina, in 1724; and many of the plants were then raised in several curious gardens in England; most, if not all of them were afterward planted in the open air, where they flourished very well for some years, and several of the plants produced flowers in the Chelsea garden for four or five years, but these were not succeeded by fruit; and in the severe frost in 1740, they were most of them destroyed, as were also the young plants which were raised from Dr. Dale's seeds the year before, which were only sheltered under a frame; so that until the Doctor sent a fresh supply of seeds in 1744, there were scarce any of the plants living in the English gardens; but since then, there has been quantities of the seeds brought to England.

This plant rises easily from seeds, if they are sown in a moderate hot-bed; the best way is to sow the seeds in pots; and plunge them into a tan-bed of a moderate warmth; and when the plants come up, and have obtained some strength, they should be gradually inured to the open air, into which they should be removed in June, and placed in a sheltered situation, where they may remain till autumn; during which time they must be kept clear from weeds, and gently refreshed with water in dry weather; but as these young plants are tender, they should be placed under a frame before the early frost comes on; for a frost in autumn will kill the tender part of their shoots, which often causes their stalks to decay most part of their length before the spring. During the winter season they should be screened from frost, but in mild weather they must enjoy the free air, otherwise their shoots will turn mouldy and decay. The following spring, just before the plants shoot, they should be carefully

turned out of the pots, so as not to break their roots; and part of them may be planted in small pots filled with light earth, and the others into a nursery-bed in a warm situation, at about four or five inches asunder; those in the pots should be plunged into a moderate hot-bed, which will forward their taking roots; but afterward must be hardened to bear the open air as before; these plants in the pots should be sheltered under a frame in winter for three or four years, till they have obtained strength; then they may be turned out of the pots, and planted in a warm situation, where they will live in the open air in common winters; but in severe frost they are in danger of being killed, if they are not sheltered; therefore the surface of the ground about their roots should be covered with old tan to keep out the frost, and their tops covered with Straw, Peas-haulm, or Fern, which will protect them.

Those plants in the beds should also be covered with mats, or Straw, in frosty weather, and after they have obtained strength, they may be transplanted into a warm situation, and treated every winter in the same manner as the other.

The leaves of this shrub were often used by Dr. Dale, in dropical cases, with very good success. A particular account of the virtues of this, and many other plants of Carolina, was sent me with dried samples of each, by the Doctor, during the last war; but as the ships were taken in their passage, they were all lost, and the Doctor dying soon after, I could never recover them.

JONTHLASPI. See CLYPEOLA.

JONQUIL. See NARCISSUS.

IPOMOEA. Lin. Gen. Plant. 199. Quamoclit. Tourn. Inst. R. H. 116. tab. 39. Quamoclit, or Scarlet Convolvulus.

The CHARACTERS are,

The flower hath a small permanent empalement, cut into five parts at the top. The petal is funnel-shaped, having a long cylindrical tube, whose brim is five-pointed, spreading open flat. It hath five awl-shaped stamina, nearly the length of the petal, terminated by roundish summits. In the bottom of the tube is situated a round germen, supporting a slender style, crowned by a roundish stigma. The germen afterward becomes a roundish capsule with three cells, inclosing three oblong seeds.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which includes those plants whose flowers have five stamina and one style.

The SPECIES are,

1. **IPOMOEA** (*Quamoclit*) foliis pinnatifidis linearibus, floribus subsolitariis. Hort. Cliff. 60. *Ipomoea with very narrow many-pointed leaves, and solitary flowers.* Quamoclit foliis tenuiter incis & pennatis. Tourn. Inst. R. H. 116. *Quamoclit with narrow, cut, winged leaves.*
2. **IPOMOEA** (*Coccinea*) foliis cordatis acuminatis, basi angulatis, pedunculis multifloris. Hort. Upsal. 39. *Ipomoea with heart-shaped pointed leaves, angular at the base, and many flowers on a stalk.* Quamoclit Americana folio hederæ flore coccineo. Com. Rar. Plant. 21. *American Quamoclit with an Ivy leaf and a scarlet flower, commonly called Scarlet Convolvulus.*
3. **IPOMOEA** (*Solanifolia*) foliis cordatis acutis integerrimis, floribus solitariis. Prod. Leyd. 430. *Ipomoea with acute, heart-shaped, entire leaves, and solitary flowers.* Quamoclit Americana folani folio, flore roseo. Plum. Cat. 3. *American Quamoclit with a Nightshade leaf, and a Rose-coloured flower.*
4. **IPOMOEA** (*Violacea*) foliis cordatis integerrimis, floribus confertis corollis indivisis. Sauv. Monsp. 114. *Ipomoea with heart-shaped entire leaves, flowers growing in clusters, and undivided petals.* Quamoclit foliis amplissimis cordiformibus. Plum. Cat. 4. *Quamoclit with large heart-shaped leaves.*
5. **IPOMOEA** (*Tuberosa*) foliis palmatis, lobis septenis lanceolatis integerrimis pedunculis trifloris. Hort. Upsal. 39. *Ipomoea with hand-shaped leaves, composed of seven spear-shaped entire lobes, and foot-stalks having three flowers.* Convolvulus major heptaphyllus, flore sulphureo odorato. Sloan. Cat. 55. *Greater seven-leaved*

I P O

Bindweed with a yellow sweet flower, called Spanish Arbour Vine.

6. IPOMOEA (*Triloba*) foliis trilobis cordatis, pedunculis trifloris. Lin. Sp. Plant. 161. *Ipomoea with heart-shaped leaves having three lobes, and three flowers on a foot-stalk.* Convolvulus pentaphyllos minor, flore purpureo. Sloan. Cat. 55. *Smaller five-leaved Bindweed with a purple flower.*
7. IPOMOEA (*Hepaticifolia*) foliis palmatis, floribus aggregatis. Flor. Zeyl. 79. *Ipomoea with hand-shaped leaves, and flowers growing in clusters.* Volubilis Zeylanica pes tigrinus dicta. Hort. Elth. 318. *Volubilis of Ceylon, called Tyger's-foot.*
8. IPOMOEA (*Digitata*) foliis digitatis glabris floribus sessilibus, caule lævi. Lin. Sp. Plant. 162. *Ipomoea with smooth hand-shaped leaves, whose lobes sit close, and a smooth stalk.* Convolvulus quinquefolius glaber Americanus. Pluk. Alm. 116. *Smooth five-leaved American Bindweed.*

The first sort grows naturally in both Indies; in the West-Indies it is called Sweet-William, and by some Indian Pink. It rises with a twining stalk seven or eight feet high, sending out many slender twining branches, which twist about any neighbouring plants for support; the leaves are winged, being composed of several pair of very fine narrow lobes, not thicker than fine sewing thread; they are about an inch long, of a deep green, and sometimes are by pairs opposite, and at others they are alternate; the flowers come out singly from the side of the stalks, standing upon slender foot-stalks about one inch long; they are funnel-shaped, having a tube an inch long, which is narrow at bottom, but gradually widens to the top, which spreads open flat, with five corners or angles: they are of a most beautiful scarlet colour, so make a fine appearance. This is an annual plant in England, but whether it is so in its native place I cannot tell; for as the seeds fall to the ground, so there is a succession of young plants, which continue flowering great part of the year.

This is a tender plant, so will not thrive in the open air in England; it is propagated by seeds, which should be sown on a hot-bed in the spring; and as the plants will soon appear, they should be each transplanted into a small pot filled with light earth, before they twine about each other, for then it will be difficult to disengage them without breaking their tops. When they are potted, they should be plunged into a new hot-bed, and sticks placed down by each plant for their stalks to twine about; after they have taken new root, they should have a good share of air in warm weather to prevent their drawing up weak; and when they are advanced too high to remain under the frame, they should be removed into the tan-bed in the stove, where they should have support, for their branches will extend to a considerable height. They will begin to flower in June, and there will be a succession of flowers till the end of September, and the seeds will ripen well in this situation every autumn.

The second sort grows naturally in Carolina and the Bahama Islands; this is also an annual plant in England, but is not so tender as the former. It hath a twining stalk, which rises six or eight feet high, garnished with heart-shaped leaves ending in acute points, which are divided into angles at their base; the flowers come out from the side of the branches, upon slender foot-stalks, which support three or four flowers of the same form and size as the former, but are not so deep coloured. There is a variety of this with Orange-coloured flowers, but they do not differ in any other respect. If the seeds of this sort are sown on a hot-bed in the spring, and when the plants come up, if they are gradually hardened, and afterward transplanted into a warm border, in favourable seasons they will flower and produce good seeds; but most people raise the plants on a very gentle hot-bed, and transplant them afterward into another; by which method they are brought forward, so will perfect their seeds earlier.

The third sort is like the second, but the leaves have

I P O

no angles, and the flowers are of a Rose colour, each foot-stalk sustaining one flower. This may be treated in the same manner as the second sort.

The fourth sort grows naturally in the West-Indies, where it twines about any neighbouring support, and rises ten or twelve feet high, garnished with large heart-shaped entire leaves: the flowers come out from the side of the branches upon slender foot-stalks, in clusters; they are of a blue colour, and their brims are not angular as in the former species, but entire. This sort is propagated by seeds, which should be sown on a hot-bed in the spring, and the plants afterward treated in the same way as is before directed for the first sort, for it is too tender to thrive in the open air here.

The fifth sort is cultivated in most of the islands in the West-Indies, but is supposed to have been introduced there from the Spanish Main. These plants rise to a very great height, and send out many branches, so are planted to cover arbours for shade in the islands, from whence it had the appellation of Spanish Arbour Vine. The stalks of this plant are covered with a purple bark; they twine about any neighbouring support, sending out many side branches, so that one plant will cover an arbour of fifty feet long. The leaves are divided into seven lobes almost to the bottom; the flowers come out from the side of the stalks; they are large, funnel-shaped, of a bright yellow colour, and smell very sweet; these are succeeded by large roundish capsules with three cells, containing one large seed in each, which are of a dark colour.

This is a perennial plant, but too tender to thrive in the open air in England; the seeds of this must be sown upon a hot-bed in the spring, and when the plants come up, they must be transplanted into separate pots, and plunged into a fresh hot-bed; but as they will soon grow too tall to stand under a frame, they should be removed into the bark-stove, where they must be supported, otherwise they will twine about all the neighbouring plants. As these plants extend their shoots to a very great length, they require a tall stove, where they may have room to grow, without which they will never produce any flowers. I have had these plants several years, but have only seen one flower produced from them; for they grow so very large before they begin to have flowers, as that few of the stoves in England have height enough for their growth.

The sixth sort grows naturally in most of the islands in the West-Indies; this hath a twining stalk, which rises ten or twelve feet high, garnished with leaves divided into three lobes, which are heart-shaped; the foot-stalks arise from the side of the stalks, each sustaining three purple flowers. This is also tender, so the plants must be raised on a hot-bed in the spring, and afterward planted in separate pots, plunging them into another hot-bed, where they may remain till they reach the glasses, when they should be removed into a glass-case where they may have room, and be screened from the cold, but should have a large share of free air admitted to them in warm weather; with this treatment the plants will flower and produce ripe seeds. The seventh sort grows naturally in India; this rises with a twining hairy stalk four or five feet high, garnished with hand-shaped leaves which are hairy, and divided at the bottom into several lobes; the flowers come out in clusters, inclosed in a five-cornered involucre; they are of a purplish colour, but small, and open only in the evening, so make no figure. This is propagated by seeds, and requires the same treatment as the sixth sort.

The eighth sort grows naturally in the West-Indies; this hath a smooth twining stalk which rises four or five feet high, garnished with hand-shaped leaves having five lobes, which sit close to the stalks; the flowers come out from the side of the stalks upon short foot-stalks, which sustain two or three purple flowers; these are succeeded by round tricapsular seed-vessels; in each cell there is one brown seed.

This

IRI

This sort requires the same treatment as the two former, with which it will produce flowers and perfect its seeds in England.

IRÉSINE. Lin. Gen. 1113. Amaranthus. Sloan. Cat. Jam. 49.

The CHARACTERS are,

It hath male and female flowers on different plants; the male flowers have an empalement composed of two neat small leaves, and five erect, small, spear-shaped petals, and five nectaries situated between the five erect stamina, which are terminated by roundish summits; the female flowers on the other plants, have the like empalement and corolla as the male, with an oval germen but no style, crowned by two roundish stigma; the empalement afterward becomes an oval capsule, inclosing woolly seeds.

This genus is ranged in the fifth order of Linnæus's twenty-second class of plants, intitled Diœcia Pentandria, from their having male and female flowers on different plants, and the male flowers having five stamina.

We know but one SPECIES of this genus, viz.

IRÉSINE (*Celosoides*.) Lin. Sp. 1456. Amaranthus panicula flavicante gracili holosericea. Sloan. Cat. Jam. 49.

Amaranthus with slender yellowish panicles of silky flowers. This plant grows naturally in Jamaica, and most of the other islands in the West-Indies, from whence I have received the seeds. It is perennial; the stalks are weak, so require support; they rise ten or twelve feet high, having large knots at each joint, garnished with oval, spear-shaped, smooth leaves. The stalks are very diffused, branching out on every side; the flowers are produced on the top, in slender loose panicles, covered with a silky down, of a pale yellow colour; these appear in July and August, and in warm seasons the seeds will ripen in the autumn.

It is propagated by seeds, which should be sown upon a hot-bed in the spring, and the plants should be afterward treated in the same manner as hath been directed for the tender sorts of Amaranthus, till they are grown too tall to remain in the frame, when they should be removed to the bark-stove, plunging the pots into the tan-bed, and supporting the branches of the plants with a trellis to prevent their falling on other plants; in this situation they will produce flowers and seeds the second year, but the plants may be continued three or four years longer.

IRIS. Tourn. Inst. R. H. 358. tab. 186, 187, 188. Lin. Gen. Plant. 57. Flower-de-luce; in French, Flambe.

The CHARACTERS are,

The flowers are inclosed in spathæ (or sheaths) which are permanent; the flowers are divided into six parts; the three outer petals are oblong, obtuse, and reflexed, the three inner are erect, and end in acute points; these all join at their base: they have three awl-shaped stamina, which lie upon the reflexed petals, and are terminated by oblong depressed summits. Under the flower is situated an oblong germen, supporting a slender style, crowned by a large three-pointed stigma; the germen afterward becomes an oblong angular capsule with three cells, filled with large seeds.

This genus of plants is ranged in the first section of Linnæus's third class, intitled Triandria Monogynia, which contains those plants whose flowers have three stamina and one style.

The SPECIES are,

1. IRIS (*Pseudoacorus*) corollis imberbibus, petalis interioribus stigmatibus minoribus, foliis ensiformibus. Hort. Cliff. Iris with an unbearded flower, the inner petals smaller than the stigma, and sword-shaped leaves. Iris palustris lutea. Tabern. Icon. 643. Yellow Marsh Flower-de-luce.
2. IRIS (*Squalens*) corollis barbatis, caule foliis longiore multifloro. Hort. Cliff. 18. Iris with bearded flowers, and the stalks longer than the leaves, having many flowers. This is the Iris vulgaris Germanica five sylvestris. C. B. P. 30. Common German, or wild Flower-de-luce.
3. IRIS (*Aphylla*) corollis barbatis, scapo nudo longitudine foliorum multifloro. Prod. Leyd. 17. Iris with a bearded flower, and a naked stalk the length of the leaves, with many flowers. Iris latifolia, caule aphylo. C. B. P.

IRI

32. Broad-leaved Flower-de-luce, whose stalks are without leaves.

4. IRIS (*Variiegata*) corollis barbatis, caule subfolioso longitudine foliorum multifloro. Prod. Leyd. 17. Iris with a bearded flower, and a leafy stalk the length of the leaves, with many flowers. Iris latifolia pannonica, colore multiplici. C. B. P. 31. Broad-leaved Hungarian Flower-de-luce of many colours.
5. IRIS (*Susiana*) corollis barbatis, caule foliis longiore unifloro. Hort. Cliff. 18. Iris with a bearded flower, and a stalk longer than the leaves, having one flower. Iris Susiana, flore maximo ex albo nigricante. C. B. P. 31. Flower-de-luce with a very large flower of a black and white colour, commonly called Chalcedonian Iris.
6. IRIS (*Biflora*) corollis barbatis, caule foliis brevior trifloro. Hort. Upsal. 17. Iris with a bearded flower, and a stalk shorter than the leaves, with three flowers. Iris humilis major, saturate purpurea biflora. Tourn. Inst. 361. Greater Dwarf Flower-de-luce of a dark purple colour, and having two flowers on each stalk.
7. IRIS (*Pumila*) corollis barbatis, caule foliis brevior unifloro. Lin. Sp. Plant. 38. Iris with a bearded flower, and a stalk shorter than the leaves, with one flower. Iris humilis minor, flore purpureo. Tourn. Inst. 361. Smaller Dwarf Flower-de-luce with a purple flower.
8. IRIS (*Germanica*) corollis barbatis, caule foliis longiore multifloro, floribus inferioribus pedunculatis. Lin. Sp. 55. Iris with a bearded flower, a stalk longer than the leaves with many flowers, and the lower flowers on foot-stalks. Iris Asiatica cærulea polyanthos. C. B. P. Blue Asiatic Flower-de-luce with many flowers, called greater Dalmatian Iris.
9. IRIS (*Orientalis*) corollis barbatis, germinibus trigonis, foliis ensiformibus longissimis caule foliis longiore bifloro. Pluk. 154. Iris with a bearded flower, a three-cornered germen, very long sword-shaped leaves, and a stalk longer than the leaves, with two flowers.
10. IRIS (*Graminea*) corollis imberbibus, germinibus sexangularibus, caule ancipiti, foliis linearibus. Hort. Cliff. 19. Iris with flowers having no beards, a six-cornered germen, a stalk having flowers on both sides, and narrow leaves. Iris angustifolia prunum reddens minor. C. B. P. 33. Smaller narrow-leaved Flower-de-luce smelling like Plums.
11. IRIS (*Maritima*) corollis imberbibus, caule foliis brevior trifloro, foliis lineari-ensiformibus. Iris whose flowers are not bearded, the stalk shorter than the leaves, having three flowers, and narrow sword-shaped leaves. Iris angustifolia maritima major. C. B. P. 33. Greater narrow-leaved maritime Flower-de-luce.
12. IRIS (*Angustifolia*) corollis imberbibus, caule foliis æqualibus multifloro, spathâ majoribus erectis. Iris whose flowers have no beards, the stalks equal in length with the leaves, having many flowers which are larger and more erect than the spathæ. Iris angustifolia, maritima minor. C. B. P. Smaller narrow-leaved maritime Flower-de-luce.
13. IRIS (*Bicolor*) corollis imberbibus, caule foliis longiore multifloro, germinibus sexangularibus, foliis linearibus. Iris whose flowers have no beards, the stalks longer than the leaves, with many flowers, a six-cornered germen, and very narrow leaves. Iris angustifolia, bicolor. C. B. P. 33. Narrow-leaved Flower-de-luce with two colours.
14. IRIS (*Sparia*) corollis imberbibus, germinibus sexangularibus, caule tereti, foliis sublinearibus. Hort. Cliff. 19. Iris whose flowers have no beards, with a six-cornered germen, a taper stalk, and very narrow leaves. Iris pratensis angustifolia, folio foetido. C. B. P. 32. Narrow-leaved Meadow Flower-de-luce, with a stinking leaf.
15. IRIS (*Sativa*) corollis imberbibus, spathâ bifoliâ, caule folioso longitudine foliorum, pedunculis longioribus. Iris with flowers having no beards, a sheath containing two leaves, a leafy stalk the length of the leaves, and longer foot-stalks to the flowers. Iris sativa lutea. C. B. P. 32. Yellow Garden Flower-de-luce.
16. IRIS (*Pisla*) corollis imberbibus, caule longitudine foliorum multifloro, foliis ensiformibus. Iris with an unbearded flower, a stalk the length of the leaves, with

I R I

many flowers, and sword-shaped leaves. *Iris humilis* minor, flore picto. Tourn. Inst. 362. *Lesser Dwarf Flower-de-luce with a painted flower.*

17. *IRIS (Verna)* corollis imberbibus, caule unifloro foliis brevioribus, radice fibrosa. Flor. Virg. 10. *Iris with an unbearded flower, a stalk shorter than the leaves, with one flower, and a fibrous root.* *Iris Virginiana* pumila five *chamaeiris verna angustifolia*, flore purpureo-caeruleo odorato. 23. *IRIS (Sambucina)* corollis barbatis, caule foliis altiore multifloro, petalis deflexis planis, erectis emarginatis. Lin. Sp. 55. *Iris with a bearded corolla, stalks taller than the leaves, having many flowers whose petals are deflexed, and the upright are indented.* *Iris latifolia Germanica*, sambuci odore. C. B. P. 31.

The first sort grows naturally in ditches and standing waters in most parts of England; this is titled in the Pharmacopeia, *Acorus adulterinus*, or *Pseudo acorus*. *Bastard Acorus*. The roots of this are pretty thick, fleshy, and spread every way near the surface of the ground; the leaves are sword-shaped, very long, of a deep green colour, and not so stiff as those of the Garden Iris; the stalks rise from two to three feet high, toward the top of which grow three or four flowers one above another, which gradually succeed each other; they are shaped like the ordinary Flower-de-luce, but the three inner petals are less than the stigmas, so they want the three upright petals which are termed standards. These appear in June, and are succeeded by large three-cornered capsules, containing three rows of flat seeds.

This sort is not cultivated in gardens, but being an officinal plant, it is here mentioned to introduce the other.

The second sort grows naturally in Germany, but has been long cultivated in the English gardens for ornament; the roots of this are very thick, fleshy, and divided into joints, spreading just under the surface of the ground; they are of a brownish colour on their outside, but white within; the leaves arise in clusters, embracing each other at their base, but spread asunder upward in form of wings; they are a foot and a half long, and two inches broad, having sharp edges, ending in points like swords; the stalks between these, which are a little longer than the leaves, having at each joint one leaf without a foot-stalk; these diminish in their size upward; the stalks divide into three branches, each of which produce two or three flowers one above another at distances, each inclosed in a

I R I

sheath; they have three large Violet-coloured petals which turn backward, and are called falls; these have beards near an inch long on their midrib toward their base, and have a short arched petal which cover the beard, with three broad erect petals of the same colour, called standards; the stamina lie upon the reflexed petals. Under each flower is situated an oblong germen, which turns to a large three-cornered capsule with three cells, filled with large compressed seeds. This flowers in June, and the seeds ripen in August.

There is a variety of this with blue standards and purple falls, which is titled *Iris hortensis latifolia*, by Caspar Bauhin; and one with pale purple standards, another with white, and a third with a smaller flower, but these are accidental varieties which have come from seeds.

The third sort has broader leaves than the last, the stalks have no leaves upon them, and are equal in length with the leaves; they have three or four large bright purple flowers, which stand above each other, having purplish sheaths or hoods; the three bending petals or falls are striped with white, from the base to the end of the beard; the flowers are succeeded by large blunt triangular capsules with three cells, filled with compressed seeds. It flowers the latter end of May, and the seeds ripen the beginning of August.

The fourth sort grows naturally in Hungary; the leaves of this are like those of the second sort, but are of a darker green; the stalks rise as tall as the leaves, and toward the bottom are garnished with one leaf at each joint, whose base embrace the stalks; the upper part is naked, and branches into three, each having two or three flowers above one another; the three upright petals or standards are yellow, and the bending petals or falls are variegated with purple stripes. This flowers in June, but is rarely succeeded by seeds in England.

The fifth sort grows naturally near Constantinople, and in other parts of the east. The leaves of this sort are not so broad as those of the second, and are of a grayish colour; the stalks rise two feet and a half high, supporting one very large flower; the three upright petals are almost as broad as a hand, but very thin, of mixed black and white stripes; the three bending petals or falls are of a darker colour, from whence some gardeners have called it the Mourning Iris. This flowers the latter end of May, or the beginning of June, but never has any seeds in England.

The sixth sort hath broad leaves like those of the second sort, but shorter; the stalks rise nine or ten inches high, branching into two or three at the top, each sustaining two deep purple flowers. This flowers in May, but is not succeeded by seeds in England.

The seventh sort hath narrower and shorter leaves than the former; the stalks are shorter than the leaves, and support one flower on the top, of a light purple colour. This flowers the beginning of May, but rarely produces seeds in this country. There are two or three varieties of this, which differ in the colour of their flowers.

The eighth sort hath the largest leaves of any of the Flower-de-luce, they are of a grayish colour and spread wide, embracing each other at their base, where they are purplish. The stalks rise near four feet high, and divide into several branches, each supporting three or four flowers above each other at distances, covered with a thin sheath; the three bending petals or falls, are of a faint purple inclining to blue, with purple veins running lengthways; the beard is yellow, and the three erect petals or standards are of a bright blue, with some faint purple stripes, the flowers have an agreeable scent. They appear the latter end of June, but are seldom succeeded by seeds in England.

The seeds of the ninth sort were brought from Carniola, by the Right Rev. Dr. Pocock, Bishop of Ossory, who found the plants growing there naturally: these were sown in the Chelsea garden, where they succeeded very well, and the plants have been since communicated to many curious gardens in Europe.

This

This plant hath a thick fleshy root, divided into many knots or tubers, which spread and multiply in the ground; these send out many strong, thick, fleshy fibres, which strike deep in the earth, putting out several smaller fibres from their sides. From these roots arise clusters of flat sword-shaped leaves of a deep green colour, which are more than three feet long, and little more than one inch broad in the broadest part, ending in points; these leaves are connected together at their base into several heads or bundles, wrapping over each other; and between these arise the flower-stalks, which grow four feet high and are jointed, having very long spathæ or sheaths at each of the upper joints, which include the flowers. These stalks generally sustain two flowers, one coming out of each sheath or spatha; these are permanent, and when the flowers are past, closely cover the seed-vessel. The flowers are divided into nine leaves, three of these stand erect, which are white, and six turn down, which are joined together at their base, the lower spreading out into a broad, obtuse, reflexed fall, having a beard which is of a bright yellow colour; the upper segment is arched over the lower, so as to form a sort of lip, which is reflexed backward; under these is situated an oblong three-cornered germen, which afterward becomes an oblong, swollen, three-cornered seed-vessel, ending in a long point, which opens into three longitudinal cells, in which the seeds are ranged; these are angular and compressed. This plant flowers the latter end of June, or the beginning of July, and the seeds ripen in the autumn. It is very hardy, and thrives well in the open air without any protection. The leaves decay to the root in the autumn, and new ones arise in the spring. The roots also propagate very fast, when they are in a light moist soil, so that it may soon be had in plenty, without waiting for plants from seeds.

The tenth sort grows naturally in Austria; this hath narrow, flat, Grass-like leaves, about a foot long, of a light green colour; between these arise the stalks about six inches high, having two narrow green leaves, which are much longer than the stalks; these stalks sustain two or three flowers, which are smaller than any of the former species; the petals have no beards, but have a broad yellow line adorned with purple stripes; the three falls are of a light purple colour striped with blue, and have a convex ridge running longitudinally, the other are of a reddish purple variegated with violet; they have a scent like fresh Plums. It flowers in July, and is succeeded by seed-vessels which are short, having three borders or wings running lengthways, opening in three cells, which are filled with angular seeds, which ripen in September.

The eleventh sort grows naturally near the sea, in the south of France, and in Italy. This hath narrow sword-shaped leaves, little more than a foot long, of a deep green colour; the stalks do not rise so tall as the leaves; they sustain at the top two or three flowers which stand near together; they are of a bright purple colour with very deep falls, and the three standards are blue; the bending petals have no beards, but instead of that white broad stripes through the middle. This flowers in July, and the seeds ripen in September.

The twelfth sort hath narrower leaves than the former, but of the same deep green colour; the stalks do not rise higher than the leaves, and support two or three flowers, which have long permanent empalements standing erect, which cover the seed-vessel till the seeds are ripe; the flowers are smaller, and of a paler colour than those of the eleventh sort.

The thirteenth sort has very narrow, long, Grass-like leaves, of a light green; the stalks rise two feet and a half high, sustaining three or four flowers above each other, which have blue falls, and purple standards striped with pale blue lines. This flowers in July, and the seeds ripen at Michaelmas.

The fourteenth sort grows naturally in Germany; this hath leaves like those of the eleventh sort, which, when broken, have a disagreeable scent; but this is

accidental, and not common to all the plants; the stalks of this are taper, and rise a little above the leaves, and sustain three or four flowers one above another, which have light blue standards, and purple variegated falls without beards; instead of which, they have a broad white line in the middle; these are succeeded by short thick capsules, which have scarce any angles, opening in three cells, which are filled with angular seeds. It flowers in July, and the seeds ripen in September.

The fifteenth sort has narrower leaves than those of the second, of a pale green colour, and not so stiff; the stalks are equal in height with the leaves, and branch out on both sides with long foot-stalks, each sustaining one pretty large yellow flower, inclosed in a long two-leaved sheath; at each joint where the foot-stalks come out there is a single leaf, which embraces the stalks with their base. This flowers in June, but rarely produces seeds in this country.

There are two varieties of this sort, one with a sulphur-coloured, and the other with a variegated flower, which are supposed to be only varieties which have been accidentally produced from seeds.

The sixteenth sort hath broad sword-shaped leaves about eight inches long; the stalks rise about the same height with the leaves, and divide into two or three foot-stalks, each sustaining two or three flowers one above another, which have yellow standards, and the falls are variegated with dark stripes. This flowers in June, but does not produce seeds here.

The seventeenth sort grows naturally in North America; this hath tufted fibrous roots, from which arise many Grass-like leaves about nine inches long; from between these come out the stalks, which are shorter than the leaves, supporting one purple flower with blue standards. This sort flowers in May, but seldom produces seeds in England.

The eighteenth sort grows also in North America; this hath narrow sword-shaped leaves about a foot long, of a light green colour; the stalks rise a little above the leaves, they are taper, and support two or three flowers one above another; the standards are of a light blue, and the falls are purple variegated, with a broad white line instead of a beard through the middle. The germen, which is situated under the flower, is three-cornered below, but taper toward the top. This flowers in June, and often produces seeds here.

The nineteenth sort grows naturally in moist places in many parts of England, so is seldom admitted into gardens. This hath thick tufted fibrous roots; the leaves are of a Grass-green, sword-shaped, and when broken emit a strong odour, not much unlike that of hot roast beef at the first scent, but if smelt too close, becomes disagreeable. It is generally called stinking Gladwyn in England; the stalks rise about the same height with the leaves, supporting two small flowers, of a purple colour, variegated. It flowers in June, and the seeds ripen in autumn.

The twentieth sort grows naturally in Austria and Bohemia; this hath narrow sword-shaped leaves near a foot and a half long, of a dark green colour; the flower-stalks rise above the leaves, and support two or three flowers with light blue standards, and deep blue falls, with a broad stripe of white, instead of the beard. This flowers in July, and the seeds ripen in September.

There are several varieties of these flag or sword-leaved Irises, which chiefly differ in the colour of their flowers, so are not to be regarded as distinct species; those which are here enumerated are supposed to be specifically different, great part of them I have cultivated by seeds, and found them constantly produce the same as the parent plants.

All these sorts are generally propagated by parting of their roots, which most of them multiply fast enough. The best time to remove and part the roots is in autumn, that they may get good root before the spring, otherwise they will not flower strong the following summer. All those sorts which spread much

at their roots should be transplanted every other year, to keep them within bounds, otherwise they will spread so much as to become troublesome, especially if they are planted near other flowers; indeed, the large growing kinds are most of them too spreading for the flower-garden, so are only fit to fill up the spaces between trees and shrubs in large plantations, where they will have a good effect during the time of their flowering.

The fifth, sixth, seventh, tenth, eleventh, sixteenth, seventeenth and eighteenth sorts, grow in less compass, so may be admitted into the large borders, or in clumps of flowers in the pleasure-garden, where they will add to the variety. The fifth sort should have a warmer situation, being a little tender, but all the other sorts will grow in almost any soil or situation; these may all be propagated by seeds, which should be sown soon after they are ripe, then the plants will come up the following spring; but if the seeds are sown in the spring, they will lie a year in the ground before they vegetate: when the plants come up they must be kept clean from weeds, and the following autumn should be transplanted into beds at ten inches or a foot distance, where they may remain till they flower, which will be the second summer after transplanting; but as most of the sorts are so easily propagated by their roots, few people care to wait for seedling plants, unless of those sorts which are scarce.

The twenty-first sort grows naturally in the islands of the Archipelago; this hath a tuberous knobbed root, from which arise five or six long, narrow, four-cornered leaves, between which arise the stalk, which supports one flower, shaped like those of the Iris, but small, and of a dark purple colour. This flowers in April, but does not produce seeds in England. It is propagated by the roots, which send out offsets; these may be taken up and transplanted when their leaves decay, but should not be kept too long out of the ground. If these are planted in a deep loose soil, the roots will run down, and be lost in a few years where they are not disturbed, so they should be annually transplanted, and have a shallow soil; they are hardy in respect to cold, and require no farther care but to keep them clean from weeds.

The twenty-second sort grows naturally in the warm parts of Europe, but is hardy enough to thrive in the open air in England; the leaves of this sort are broad, of a pale green colour; the flower-stalks rise taller than the leaves, supporting one or two white flowers which sit close to the stalks. The roots of this are used in medicine, and is usually called Sweet Iris.

The twenty-third sort hath broad leaves, of a deeper green than those of the last sort. The stalks rise much above the leaves, each having four or five flowers, which have a yellow ground, variegated with dark brown stripes, and have a scent like Elder; the two sorts flower the latter end of May, or beginning of June.

They are so hardy as to thrive as well as the second sort in the open air in this country, and may be propagated by parting of their roots, or by seeds, in the same way as is directed for that sort.

IRIS Persica.

} See XIPHIMUM.

ISATIS. Tourn. Inst. R. H. 211. tab. 100. Lin. Gen. Plant. 738. Woad; in French, *Pastel*.

The CHARACTERS are,

The empalement of the flower is composed of four oval coloured leaves, which spread open and fall away. The flower hath four oblong petals, placed in form of a cross, which are narrow at their base, but broad and obtuse at their ends. It hath six stamina, four of which are as long as the petals, the other two are shorter; these are terminated by oblong lateral summits. It has an oblong compressed germen, the length of the two shorter stamina, crowned by an obtuse stigma. The germen becomes an oblong compressed pod with one cell, opening with two valves, inclosing one oval compressed seed in the center.

This genus of plants is ranged in the second section of Linnæus's fifteenth class, intitled Tetradynamia

Siliquosa, which includes the plants whose flowers have four long and two shorter stamina, and their seeds in pods.

The SPECIES are,

1. ISATIS (*Tinctoria*) foliis radicalibus oblongo-ovatis obtusis integerrimis, caulinis sagittatis filiculis oblongis. *Woad with oblong, oval, blunt, entire leaves at bottom, but those on the stalks arrow-pointed, and oblong pods. Isatis sativa vel latifolia. C. B. P. 113. Broad-leaved cultivated Woad.*
2. ISATIS (*Dalmatica*) foliis radicalibus lanceolatis crenatis, caulinis lineari-sagittatis, filiculis brevioribus emarginatis. *Woad with spear-shaped lower leaves which are slightly crenated, those on the stalks very narrow and arrow-pointed, and shorter indented pods. Isatis Dalmatica major. Bobart. Greater Woad of Dalmatia.*
3. ISATIS (*Lusitanica*) foliis radicalibus crenatis, caulinis sagittatis, pedunculis subtomentosis. Lin. Sp. 936. *Woad with crenated lower leaves, those on the stalks balbert-shaped, and the foot-stalks of the flowers woolly. Isatis sylvestris, minor Lusitanica. H. L. App. Smaller wild Portugal Woad.*
4. ISATIS (*Egyptiaca*) foliis omnibus dentatis. Lin. Sp. 937. *Woad whose leaves are all indented.*

The first sort is cultivated in several parts of England for the purposes of dyeing, this being used as a foundation for many of the dark colours.

This is a commodity well worth propagating in all places where the land is suitable for it, which must be a pretty strong soil, but not too moist.

The plant is biennial, in which it differs from the third and fourth sort, which are annual. The lower leaves of this are of an oblong oval figure, and pretty thick consistence, when growing in a proper soil; they are narrow at their base, but broad above, and end in obtuse roundish points, entire on their edges, and of a lucid green. The stalks rise near four feet high, dividing into several branches, garnished with arrow-shaped leaves, sitting close to the stalks; the ends of the branches are terminated by small yellow flowers, in very close clusters, which are composed of four small petals, placed in form of a cross; these are succeeded by pods shaped like a bird's tongue, half an inch long, and one eighth of an inch broad, which when ripe turn black, and open with two valves, having one cell, in which is situated a single seed. It flowers in July, and the seeds ripen the beginning of September.

The third sort has been supposed to be the same species as the first, only differing by culture; but I have propagated both sorts more than forty years, and have not found either of them alter; there are also very essential differences between the two plants, particularly in the shape of the under leaves, which in the wild sort are narrow and spear-shaped, and those on the stalks are not more than half the breadth of those of the cultivated Woad. The stalks do not branch so much, and the pods are narrower than those of the other sort, nor do the roots abide so long, for they generally die the same year.

The second sort grows naturally in Dalmatia; this is a biennial plant; the lower leaves are spear-shaped, and crenated on their edges, but those on the stalks are very narrow and arrow-pointed. The stalks branch more than those of the first sort, and rise higher. The flowers are larger, and of a brighter yellow colour. The seed-vessels are shorter, and broader at their ends, which are indented. These plants all flower in July, and their seeds ripen in September.

The fourth sort grows naturally in Egypt, and is an annual plant, which is too tender to thrive in the open air in England, therefore the seeds should be sown on a hot-bed in the spring; and when the plants are fit to remove they must be transplanted on a fresh hot-bed to bring them forward, but as soon as they have taken new root, they should have a large share of fresh air admitted to them daily, to prevent their being drawn up weak. In this bed they may remain five or six weeks, by which time they will be fit to transplant into pots, which should be carefully performed, not

to let the earth fall from their roots; the pots should also be plunged into a moderate hot-bed, giving the plants plenty of air at all times when the weather will permit, and supporting their stalks, which will otherwise trail on the ground; with this management the plants will flower in June, and ripen their seeds in September.

The three last sorts are not cultivated for use, so are only preserved in botanic gardens for the sake of variety; the second and third sorts are propagated by seeds, which should be sown in autumn; and when the plants come up, they must be thinned, leaving them six inches apart; afterward they must be kept clean from weeds: the summer following they will flower and produce ripe seeds, after which these sorts soon decay; the roots of the first sort will live another year. The first sort which is propagated for use, is sown upon fresh land which is in good heart, for which the cultivators of Woad pay a large rent; they generally chuse to have their land situated near great towns, where there is plenty of dressing, but they never stay long on the same spot, for the best ground will not admit of being sown with Woad more than twice; for if it is oftener repeated, the crop seldom pays the charges of culture, &c.

Those who cultivate this commodity, have gangs of people, who have been bred to this employment, so that whole families travel about from place to place, wherever their principal fixes on land for the purpose; but these people go on in one track, just as their predecessors taught them; nor have their principals deviated much from the practice of their ancestors, so that there is a large field for improvement, if any of the cultivators of Woad were persons of genius, and could be prevailed on to introduce the garden culture so far as it may be adapted to this plant; this I know from experience, having made numbers of trials in the culture of this plant, therefore I shall insert them here for the benefit of those who may have ingenuity enough to strike out of the old beaten track.

As the goodness of Woad consists in the size and fatness of the leaves, the only method to obtain this, is by sowing the seed upon ground at a proper season, and allow the plants proper room to grow, as also to keep them clean from weeds; which, if permitted to grow, will rob the plants of their nourishment. The method practised by some of the most skilful kitchen-gardeners in the culture of Spinach, would be a great improvement to this plant, for some of them have improved the round-leaved Spinach so much by culture, as to have the leaves more than six times the size they were formerly; and their fatness has been in the same proportion, upon the same land, which has been effected by thinning of the plants when young, and keeping the ground constantly clean from weeds; but to return to the culture of Woad.

After having made choice of a proper spot of land, which should not be too light and sandy, nor over stiff and moist, but rather a gentle hazel loam, whose parts will easily separate: the next is to plough this up just before winter, laying it in narrow high ridges, that the frost may penetrate through the ridges, to mellow and soften the clods; then in the spring plough it again crossway, laying it again in narrow ridges; after it has lain some time in this manner, and the weeds begin to grow, it should be well harrowed to destroy them; this should be twice repeated while the weeds are young, and if there are any roots of large perennial weeds, they must be harrowed out, and carried off the ground. In June the ground should be a third time ploughed, when the furrows should be narrow, and the ground stirred as deep as the plough will go, that the parts may be as well separated as possible; and when the weeds appear again, the ground should be well harrowed to destroy them. Toward the end of July, or the beginning of August, it should be ploughed the last time, when the land should be laid smooth, and when there is a prospect of showers, the

ground must be harrowed to receive the seeds, which should be sown either in rows with the drill plough, or in broad-cast, after the common method; but it will be proper to steep the seeds one night in water before they are sown, which will prepare them for vegetation: if the seeds are sown in drills with a plough, they will be covered by an instrument fixed to the plough for that purpose; but those which are sown broad-cast in the common way, must be well harrowed in. If the seeds are good and the season favourable, the plants will appear in a fortnight, and in a month or five weeks after will be fit to hoe; for the sooner this is performed when the plants are distinguishable, the better they will thrive, and the weeds being then young, will be soon destroyed. The method of hoeing these plants is the same as for Turneps, with this difference only, that these plants need not be thinned so much; for at the first hoeing, if they are separated to the distance of three or four inches, and at the last to six inches, it will be space enough for the growth of the plants; if this is carefully performed, and in dry weather, most of the weeds will be destroyed: but as some of them may escape in this operation, and young weeds will arise, so the ground should be a second time hoed in October, always chusing a dry time for this work; at this second operation, the plants should be singled out to the distance they are to remain. After this the ground will be clean from weeds till the spring, when young weeds will come up, therefore about a fortnight in April will be a good time to hoe the ground again, when the weeds will be young, so may be performed in less than half the time it would require if the weeds were permitted to grow large, and the sun and wind will much sooner kill them; this hoeing will also stir the surface of the ground, and greatly promote the growth of the plants; if it is performed in dry weather, the ground will be clean till the first crop of Woad is gathered, after which it must be again well cleaned; if this is carefully repeated, after the gathering of each crop, the land will always lie clean, and the plants will thrive the better. The expence of the first hoeing will be about six shillings per acre; and for the after-hoeings half that price will be sufficient, provided they are performed when the weeds are young; for if they are suffered to grow large, it will require more labour, nor can it be so well performed; therefore it is not only the best husbandry to do this work soon, but it will be found the cheapest method; for the same number of men will hoe a field of ten acres three times, when it is performed while the weeds are young, as is required to hoe it twice only, because the weeds have longer time to grow between the operations.

If the land in which the seed is sown, should have been in culture before for other crops, so not in good heart, it will require dressing before it is sown, in which case rotten stable dung is preferable to any other; but this should not be laid on till the last ploughing before the seeds are sown, and not spread but as the land is ploughed, that the sun may not exhale the goodness of it, which in summer is soon lost, when spread on the ground. The quantity should not be less than twenty loads to each acre, which will keep the ground in heart till the crop of Woad is spent.

The time for gathering the crop is according to the season, but it should be performed as soon as the leaves are fully grown, while they are perfectly green; for when they begin to change pale, great part of their goodness is over; for the quantity will be less, and the quality greatly diminished.

If the land is good, and the crop well husbanded, it will produce three or four gatherings, but the two first are the best; these are commonly mixed together in the manufacturing of it, but the after-crops are always kept separate; for if these are mixed with the other, the whole will be of little value. The two first crops will sell from twenty-five to thirty pounds a ton; but the latter will not bring more than seven or eight pounds, and sometimes not so much.

I S O

An acre of land will produce a ton of Woad, and in good seasons near a ton and a half.

When the planters intend to save the seeds, they cut three crops of the leaves, and then let the plants stand till the next year for seed; but if only one crop is cut, and that only of the outer leaves, letting all the middle leaves stand to nourish the stalks, the plants will grow stronger, and produce a much greater quantity of seeds.

These seeds are often kept two years, but it is always best to sow new seeds when they can be obtained. The seeds ripen in August; when the pods turn to a dark colour, the seeds should be gathered; it is best done by reaping the stalks in the same manner as Wheat, spreading the stalks in rows upon the ground, and in four or five days the seeds will be fit to thresh out, provided the weather is dry; for if it lies long, the pods will open and let out the seeds.

There are some of the Woad planters who feed down the leaves in winter with sheep, which is a very bad method; for all plants which are to remain for a future crop, should never be eaten by cattle, for that greatly weakens the plants; therefore those who eat down their Wheat in winter with sheep are equally blameable.

ISOPYRUM. Lin. Gen. Plant. 621. Helleborus. Amman.

The CHARACTERS are,

The flower has no empalement. It hath five equal oval petals, which fall off, and five short tubulous nectarii, situated within the petals, divided at their brim into three lobes, the middle one being the largest. It hath a great number of short hairy stamina, terminated by single summits, and several oval germen, with single styles of the same length, crowned by an obtuse stigma the length of the stamina. The germen afterward become so many recurved capsules with one cell, filled with small seeds.

This genus of plants is ranged in the seventh section of Linnæus's thirteenth class, intitled Polyandria Polygynia, which includes those plants whose flowers have many stamina and styles.

The SPECIES are,

1. **ISOPYRUM** (*Fumaroides*) stipulis subulatis, petalis acutis. Hort. Upsal. 157. *Isopyrum with awl-shaped stipule, and acute petals.* Helleborus fumaricæ foliis. Amman. Ruth. 57. tab. 12. *Hellebore with Fumitory leaves.*
2. **ISOPYRUM** (*Thalicroides*) stipulis ovatis, petalis obtusis. Lin. Sp. Plant. 557. *Isopyrum with oval stipule, and obtuse petals.* Ranunculus nemorosus, thalictri folio. C. B. P. 178. *Wood Crowsfoot with a Meadow Rue leaf.*
3. **ISOPYRUM** (*Aquilegioides*) stipulis obsoletis. Lin. Sp. Plant. 557. *Isopyrum with obsolete stipule.* Aquilegia montana, flore parvo, thalictri folio. C. B. P. 144. *Mountain Columbine with a small flower, and Meadow Rue Leaf.*

The first sort grows naturally in Siberia, from whence the seeds were sent to the Imperial garden at Peterburgh, and the late Dr. Amman, professor of botany there, sent me part of the seeds; this is an annual plant, which seldom rises more than three or four inches high. The leaves are shaped like those of Fumitory; they are small, and of a gray colour. The stalk is naked to the top, where there is a circle of leaves just under the flowers. The flowers are small, of an herbaceous colour on their outside, but yellow within, having five acute petals, and as many honey glands, with a great number of stamina which are shorter than the petals, and several reflexed moon-shaped germen, having so many single styles, crowned by obtuse stigmas. The flowers are succeeded by many recurved seed-vessels with one cell, filled with small shining black seeds. It flowers the beginning of April, and the seeds ripen in May, then the plants decay.

The seeds of this plant should be sown in a shady border soon after they are ripe, for when they are kept long out of the ground, they seldom grow the first year; therefore when the seeds are permitted to

I T E

scatter, they succeed better than those which are sown, and the plants will require no other care but to keep them clean from weeds; as there is no great beauty in this plant, so a small patch or two of them in any shady part of the garden, by way of variety, will be sufficient.

The second and third sorts were sent me from Verona, near which place they grow naturally. The second sort hath leaves very like those of the smallest Meadow Rue. The stalks rise four or five inches high, supporting a few small white flowers, with obtuse petals, containing many small seeds. It flowers the latter end of March, and the seeds ripen in May.

The third sort hath leaves like the second, but a little larger, and of a greener colour. The stalks rise about six inches high, supporting two or three small white flowers, shaped like those of the second sort; these are succeeded by recurved seed-vessels, filled with small seeds. It flowers in April, and the seeds ripen in June.

Both these plants delight in a moist shady situation; they are propagated by seeds in the same way as the first sort, but these will live two or three years.

ISORA. See HELICTERES.

ITEA. Lin. Gen. Plant. 243. Flor. Virg. 143. Dictonangia. Mitch. Gen. 5.

The CHARACTERS are,

The empalement of the flower is small, permanent, and erect, ending in five acute points. The flower has five petals, which are inserted in the empalement. It hath five awl-shaped stamina inserted in the empalement, which are as long as the petals, terminated by roundish summits, and an oval germen supporting a cylindrical style, which is permanent, crowned by an obtuse stigma. The germen afterward becomes a long oval capsule, with the style at the top, having one cell filled with small seeds.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which includes those plants whose flowers have five stamina and one style.

We have but one SPECIES of this genus, viz.

ITEA (*Virginica*.) Flor. Virg. 143. We have no English title for this plant,

This shrub grows in moist soils in several parts of North America, where it rises to the height of six or seven feet, sending out many branches from the ground upward, garnished with spear-shaped leaves placed alternately, slightly sawed on their edges, which are reflexed, veined, and of a light green. At the extremity of the same year's shoots, in the month of July, are produced fine spikes of white flowers, three or four inches long, erect; and when these shrubs are in vigour, they will be entirely covered with these spikes of flowers, so that they make a fine appearance at their season of flowering.

This shrub is now pretty common in England; but the garden where I have seen it in the greatest vigour, is that of his late Grace the Duke of Argyle, at Whitton, near Hounslow, where the soil agrees so well with this plant, that it thrives and flowers there as well as in its native country.

This shrub will live in the open air in England, the cold never injuring it, but it will not thrive upon dry gravelly ground, being very apt to die in such places in the summer season. It is propagated by layers, which, if laid down in the autumn, will put out roots so as to be fit to remove by the following autumn; when they may be transplanted into a nursery, or to the place where they are to remain. This shrub flowers at a season when there are few others in beauty, so it is the more valuable on that account.

IVA. Lin. Gen. 1059. Tarconanthus. Vail. Act. Par. 1719.

The CHARACTERS are,

It hath male and female flowers in the same plant; the flowers have a roundish permanent empalement, including several florets, which are convex; the male flowers have one petal, which is funnel-shaped, and indented in five parts at the brim; these are situated in the disk; they have five bristly stamina, terminated by erect summits, approach-

ing each other; the female half florets have neither petal or stamina; they have an oblong germen supporting two hair-like styles, crowned with acute stigmas. The empalement afterward becomes the capsule, including one naked seed.

This genus of plants is ranged in the fifth section of Linnæus's twenty-first class, intitled Monœcia Pentandria, from the plants having male and female florets, and the male florets having five stamina.

The SPECIES are,

1. IVA (*Annua*) foliis lanceolato-ovatis, caule herbaceo. Hort. Upsal. 285. Ivy with oval spear-shaped leaves and an herbaceous stalk. Tarconanthus foliis cordatis ferratis trinervis. Prod. Leyd. 538.

2. IVA (*Frutescens*) foliis lanceolatis, caule fruticoso. Amœn. Acad. 3. p. 25. Ivy with spear-shaped leaves and a shrubby stalk. Agerato affinis; Peruviana frutescens. Pluk. Alm. 12.

The first sort grows naturally in many parts of the West-Indies; it is an annual plant, with an herbaceous stalk, which rises from two to three feet high, sending out several branches from the sides, which are garnished with oval spear-shaped leaves, having three deep longitudinal veins, and are sawed on their edges; the stalks and branches are terminated by small clusters of pale blue flowers, which appear in July, and are succeeded by seeds which ripen in the autumn.

This is propagated by seeds, which should be sown in the spring upon a moderate hot-bed: and when the plants are fit to remove, they should be transplanted on another hot-bed to bring them forward, treating them in the same way as is directed for Impatiens, with which management the plants will flower and perfect their seeds.

The second sort has been long an inhabitant of the English gardens, where it has been known by the title of Jesuits Bark-tree. It hath slender ligneous branches which rise eight or ten feet high, garnished with spear-shaped sawed leaves; the branches (in warm seasons) are terminated by small clusters of flowers, of a pale purple colour, which appear the latter end of August, but are not succeeded by seeds in England.

This shrub was some years past preserved in green-houses, being supposed too tender to live through the winter in the open air; but late trials have made it appear, that the ordinary winters in England seldom hurt it, provided it is planted in a dry soil and a sheltered situation. It is propagated in the nursery-gardens about London for sale, and if the branches are layed into the ground in the spring, they will put out roots in six months; or if cuttings are planted in a shady border in May, they will take root.

JUDAICA ARBOR. See CERCIS.

JUGLANS. Lin. Gen. Plant. 950. Nux. Tourn. Inst. R. H. 581. tab. 346. Walnut; in French, *Noisetier*.

The CHARACTERS are,

It hath male and female flowers at separate distances on the same tree. The male flowers are disposed in an oblong rope, or catkin, which is cylindrical and imbricated, with spaces between the scales; each scale has one flower, with one petal fixed in the outer center, toward the outside of the scale. The petal is divided into six equal parts; in the center is situated many short stamina, terminated by erect acute summits. The female flowers grow in small clusters, sitting close to the branches; these have a short, erect, four-pointed empalement, sitting on the germen, and an acute erect petal, divided into four parts. Under the empalement sits a large oval germen, supporting two short styles, crowned by large reflexed stigmas. The germen afterward becomes a large oval dry berry, with one cell, inclosing a large oval nut with netted furrows, whose kernel hath four lobes, which are variously furrowed.

This genus of plants is ranged in the eighth section of Linnæus's twenty-first class, intitled Monœcia Polyandria, including those plants which have male and female flowers on the same plant, and the male flowers have many stamina.

The SPECIES are,

1. JUGLANS (*Regia*) foliolis ovalibus glabris subferratis subæqualibus. Hort. Cliff. 449. Walnut with oval small leaves or lobes, which are smooth, sawed, and equal. Nux juglans five Regia vulgaris. C. B. P. 417. Common Walnut.
2. JUGLANS (*Nigra*) foliolis quindenis lanceolatis ferratis, exterioribus minoribus gemmulis super axillariibus. Lin. Sp. 1415. Walnut-tree with spear-shaped lobes which are sharply sawed, the middle being the largest. Nux juglans Virginiana nigra. H. L. 452. Black Virginia Walnut.
3. JUGLANS (*Oblonga*) foliolis cordato-lanceolatis inferne nervosis, pediculis foliorum pubescentibus. Walnut with heart spear-shaped lobes, having many veins on their under side, and downy foot-stalks to the leaves. Juglans nigra, fructu oblongo profundissime insculpto. Cat. Hort. Chelf. Black Virginia Walnut, with an oblong fruit very deeply furrowed.
4. JUGLANS (*Alba*) foliolis lanceolatis ferratis, exterioribus latioribus. Lin. Sp. Plant. 997. Walnut with spear-shaped sawed lobes, the outer being the broadest. Nux juglans alba Virginienfis. Park. Theat. 1414. White Virginia Walnut called Hickory Nut.
5. JUGLANS (*Glabra*) foliolis cuneiformibus ferratis, exterioribus majoribus. Walnut with wedge-shaped lobes which are sawed, the outer being the largest. Juglans alba fructu minori cortice glabro. Clayt. Flor. Virg. White Walnut with a smaller fruit, and a smooth bark.
6. JUGLANS (*Ovata*) foliolis lanceolatis ferratis glabris subæqualibus. Walnut with smooth, spear-shaped, sawed lobes, which are equal. Juglans alba fructu ovato compresso, nucleo dulce, cortice squamoso. Clayt. Flor. Virg. White Walnut with an oval compressed fruit, a sweet kernel, and a scaly bark, commonly called Shag-bark in America.

There are several varieties of the common Walnut, which are distinguished by the following titles: the large Walnut, the thin shelled Walnut, the French Walnut, the late ripe Walnut, and the double Walnut; but these do all of them vary when raised by the seed, so that the nuts from the same tree will produce plants whose fruit will differ; therefore there can be no dependence upon the trees which are raised from nuts, till they have produced fruit; so that those persons who plant the trees for their fruit, should make choice of them in the nurseries when they have their fruit upon them, otherwise they may be deceived, by having such as they would not chuse.

The second sort is commonly called Black Virginia Walnut; this grows to a large size in North America. The leaves of this sort are composed of five or six pair of spear-shaped lobes, which end in acute points, and are sawed on their edges; the lower pair of lobes are the least, the other gradually increase in their size to the top, where the pair at the top, and the single lobe which terminates the leaf, are smaller; these leaves, when bruised, emit a strong aromatic flavour, as do also the outer cover of the nuts, which are rough, and rounder than those of the common Walnut. The shell of the nut is very hard and thick, and the kernel small, but very sweet.

The third sort grows naturally in North America, where the trees grow to a large size. The leaves of this sort are composed of seven or eight pair of long heart-shaped lobes, broad at their base, where they are divided into two round ears, but terminate in acute points; they are rougher, and of a deeper green than those of the second sort, and have nothing of the aromatic scent which they have. The fruit is very long. The shell is deeply furrowed, and is very hard. The kernel is small, but well flavoured.

The fourth sort is very common in most parts of North America, where it is called Hickory Nut. The leaves of this sort are composed of two or three pair of oblong lobes, terminated by an odd one; these are of a light green, and sawed on their edges; the lower pair of lobes are the smallest, and the upper the largest. The fruit is shaped like the common Wal-

J U G

nut; but the shell is not furrowed, and is of a light colour.

The fifth sort is not so large as the fourth. The leaves are composed of two pair of lobes, terminated by an odd one; these are narrow at their base, but broad and rounded at their ends; they are sawed on their edges, and are of a light green. The nuts are small, have a smooth shell, and are very hard and white.

The sixth sort grows naturally in North America, where it rises to a middling stature. The leaves of this sort are composed of three pair of smooth spear-shaped lobes, of a dark green colour, sawed on their edges, and ending in acute points. The fruit is oval, the shell white, hard, and smooth; the kernel small, but very sweet. The young shoots of the tree are covered with a very smooth brownish bark, but the stems and older branches have a rough scaly bark, from whence it had the appellation of Shagbark, in America.

The common Walnut is propagated in many parts of England for the fruit, and formerly the trees were propagated for their wood, which was in very great esteem, till the quantity of Mahogany, and other useful woods which have been of late years imported into England, have almost banished the use of Walnut.

These trees are propagated by planting their nuts, which, as was before observed, seldom produce the same sort of fruit as are sown; so that the only way to have the desired sort, is to sow the nuts of the best kinds; and if this is done in a nursery, the trees should be transplanted out when they have had three or four years growth, to the place where they are designed to remain; for these trees do not bear transplanting when they are of a large size, therefore there may be a good number of the trees planted, which need not be put at more than six feet apart, which will be distance enough for them to grow till they produce fruit; when those whose fruit are of the desired kind may remain, and the others cut up, to allow them room to grow; by this method a sufficient number of the trees may be generally found among them to remain, which will thrive and flourish greatly when they have room; but as many people do not care to wait so long for the fruit, so the next best method is to make choice of some young trees in the nurseries, when they have their fruit upon them; but though these trees will grow and bear fruit, yet they will never be so large or so long lived, as those which are planted young.

All the sorts of Walnuts which are propagated for timber, should be sown in the places where they are to remain; for the roots of these trees always incline downward, which being stopped or broken, prevent their aspiring upward, so that they afterwards divaricate into branches, and become low spreading trees; but such as are propagated for fruit, are greatly mended by transplanting; for hereby they are rendered more fruitful, and their fruit are generally larger and fairer; it being a common observation, that downright roots greatly encourage the luxuriant growth of timber in all sorts of trees; but such trees as have their roots spreading near the surface of the ground, are always the most fruitful and best flavoured.

The nuts should be preserved in their outer covers in dry sand until February, when they should be planted in lines, at the distance you intend them to remain; but in the rows they may be placed pretty close, for fear the nuts should miscarry; and the young trees, where they are too thick, may be removed, after they have grown two or three years, leaving the remainder at the distance they are to stand.

In transplanting these trees, you should observe never to prune either their roots or large branches, both which are very injurious to them; nor should you be too busy in lopping or pruning the branches of these trees when grown to a large

J U G

size, for it often causes them to decay; but when there is a necessity for cutting any of their branches off, it should be done early in September (for at that season the trees are not so subject to bleed) that the wound may heal over before the cold increases; the branches should always be cut off quite close to the trunk, otherwise the stump which is left will decay, and rot the body of the tree.

The best season for transplanting these trees is as soon as the leaves begin to decay, at which time if they are carefully taken up, and their branches preserved entire, there will be little danger of their succeeding, although they are eight or ten years old, as I have several times experienced; though, as was before observed, these trees will not grow so large, or continue so long, as those which are removed young. This tree delights in a firm, rich, loamy soil, or such as is inclinable to chalk or marl; and will thrive very well in stony ground, and on chalky hills, as may be seen by those large plantations near Leatherhead, Godstone, and Carshalton in Surry, where are great numbers of these trees planted upon the downs, which annually produce large quantities of fruit, to the great advantage of their owners; one of which I have been told, farms the fruit of his trees, to those who supply the markets, for 30 l. per annum.

The distance these trees should be placed, ought not to be less than forty feet, especially if regard be had to their fruit; though when they are only designed for timber, if they stand much nearer, it promotes their upright growth. The black Virginia Walnut is much more inclinable to grow upright than the common sort, and the wood being generally of a more beautiful grain, renders it preferable to that, and better worth cultivating. I have seen some of this wood which hath been beautifully veined with black and white, which, when polished, has appeared at a distance, like veined marble. This wood is greatly esteemed by the cabinet-makers for inlaying, as also for bedsteads, stools, tables, and cabinets; and is one of the most durable woods for those purposes of English growth, being less liable to be infected with insects than most other kinds (which may proceed from its extraordinary bitterness;) but it is not proper for buildings of strength, it being of a brittle nature, and exceeding subject to break very short, though it commonly gives notice thereof, by its cracking some time before it breaks.

The general opinion is, that the beating of this fruit improves the trees, which I do not believe, since in the doing of this, the younger branches are generally broken and destroyed; but as it would be exceeding troublesome to gather it by hand, so in beating it off, great care should be taken that it be not done with violence, for the reason before assigned. In order to preserve the fruit, it should remain upon the trees till it is thorough ripe, when it should be beaten down, and laid in heaps for two or three days; after which they should be spread abroad, when, in a little time, their husks will easily part from the shells; then you must dry them well in the sun, and lay them up in a dry place, where mice or other vermin cannot come to them, in which place they will remain good for four or five months; but there are some persons who put their Walnuts into an oven gently heated, where they let them remain four or five hours to dry, and then put them up in oil jars, or any other close vessel, mixing them with dry sand, by which method they will keep good six months. The putting of them in the oven is to dry the germ, and prevent their sprouting; but if the oven be too hot it will cause them to shrink, therefore great care must be had to that.

All the other sorts are propagated in the same way, but as few of the sorts produce fruit in England, so their nuts must be procured from North America; which should be gathered when fully ripe, and put up in dry sand, to preserve them in their passage to England: when they arrive here, the sooner they are planted the greater chance there will be of their succeeding;

ceeding; when the plants come up, they should be kept clean from weeds; and if they shoot late in the autumn, and their tops are full of sap, they should be covered with mats, or some other light covering, to prevent the early frosts from pinching their tender shoots, which often causes them to die down a considerable length before the spring; but if they are screened from these early frosts, the shoots will become firmer and better able to resist the cold. Some of these sorts are tender while young, so require a little care for the two first winters, but afterward will be hardy enough to resist the greatest cold of this country.

The black Virginia Walnut is full as hardy as the common sort: there are some large trees of this kind in the Chelsea garden, which have produced great quantities of fruit upward of forty years; the nuts have generally ripened so well there as to grow, but their kernels are small, so are of little value.

The trees all require the same culture as the common Walnut, but they grow best in a soft loamy soil not too dry, and where there is a depth of soil for their roots to run down. The Hickory, when young, is very tough and pliable, so the sticks of it are much esteemed; but the wood when grown large is very brittle, so not of any great use. The black Virginia Walnut is the most valuable wood of all the sorts; some of the trees are beautifully veined, and will take a good polish, but others have very little beauty, which is the case of many other sorts of wood.

JUJUBE. See ZIZIPHUS.

JULIANS, or ROCKETS. See HESPERIS.

JULY FLOWER. See DIANTHUS.

JUNCUS. Tourn. Inst. R. H. 246. tab. 127. Lin. Gen. Plant. 396. Rush; in French, *Jonc*.

The CHARACTERS are,

It hath a chaff opening with two valves, an empalement with six oblong pointed little leaves which are permanent; the flower hath no petals, but the coloured empalement is by some taken for petals. It hath six short hairy stamina, terminated by oblong erect summits, and a three-cornered pointed germen, with a short slender style, crowned by three long, hairy, slender stigmas, which are reflexed. The germen afterward becomes a close three-cornered capsule with one cell, opening with three valves, inclosing roundish seeds.

This genus of plants is ranged in the first section of Linnæus's sixth class, intitled Hexandria Monogynia, which contains the plants whose flowers have six stamina and one style.

The SPECIES are,

1. **JUNCUS** (*Acutus*) culmo subnudo tereti mucronato, paniculâ terminali, involucrio diphylllo spinoso. Lin. Sp. Plant. 325. *Rush with a naked, taper, pointed stalk, terminated by a panicle, and a prickly two-leaved involucrium.* Juncus acutus, capitulis sorghi. C. B. P. 11. *Prickly large Sea Rush.*
2. **JUNCUS** (*Filiformis*) culmo nudo, apice membranaceo incurvo, paniculâ laterali. Lin. Sp. Plant. 326. *Rush with a naked stalk, an incurved membranaceous apex, and a lateral panicle.* Juncus acutus, panicula sparsa. C. B. P. *Common hard Rush.*
3. **JUNCUS** (*Effusus*) culmo nudo stricto, paniculâ laterali. Flor. Leyd. 44. *Rush with a naked close stalk, and a lateral panicle.* Juncus lævis, paniculâ sparsâ, major. C. B. P. *Larger common soft Rush, with a spreading panicle.*
4. **JUNCUS** (*Conglomeratis*) culmo nudo stricto, capitulo laterali. Prod. Leyd. 44. *Rush with a close naked stalk and lateral heads.* Juncus lævis, paniculâ non sparsâ. C. B. P. *Soft Rush with a more compact panicle.* There are many other species of this genus, some of which grow naturally in England, and are very troublesome weeds in many places, so are not worthy of being enumerated here; and those which are here mentioned, is only to point out a method of destroying them.

The first and second sorts grow on the sea-shores, where they are frequently watered by the salt water. These two sorts are planted with great care on the

banks of the sea in Holland, in order to prevent the water from washing away the earth; which being very loose, would be in danger of removing every tide, if it were not for the roots of these Rushes, which fasten themselves very deep in the ground, and mat themselves near the surface, so as to hold the earth closely together. Therefore, whenever the roots of these Rushes are destroyed, the inhabitants immediately repair them to prevent farther damage. In the summer time, when the Rushes are fully grown, the inhabitants cut them, and tie them up into bundles, which are dried, and afterward carried into the larger towns and cities, where they are wrought into baskets, and several other useful things, which are frequently sent into England. These sorts do not grow so strong in England, as they do on the Maese, and some other places in Holland, where I have seen them upward of four feet high.

The third and fourth sorts grow on moist, strong, uncultivated lands in most parts of England, and consume the herbage where they are suffered to remain. The best method of destroying these Rushes is, to fork them up clean by the roots in July, and after having let them lie a fortnight or three weeks to dry, to lay them in heaps, and burn them gently; and the ashes which these afford, will be good manure for the land; but in order to prevent their growing again, and to make the pasture good, the land should be drained, otherwise there will be no destroying these Rushes entirely; but after it is well drained, if the roots are annually drawn up, and the ground kept duly rolled, they may be subdued.

JUNIPERUS. Tourn. Inst. R. H. 588. tab. 361. Lin. Gen. Plant. 1005. Juniper; in French, *Genévrier*.

The CHARACTERS are,

It hath male and female flowers in different plants, and sometimes at separate distances on the same plant. The male flowers grow on a conical katkin; the flowers are placed by threes, two of them fastened along the common tail opposite, terminated by a single one; the scales are broad, short, lying over each other, and fixed to the column by a very short foot-stalk. The flower has no petal, but three stamina in the male flower which are joined in one body below, having three distinct summits, adbering to the scales of the lateral flowers. The female flowers have a small three-pointed empalement sitting upon the germen, which is permanent; they have three stiff, acute, permanent petals; the germen sitting below the empalement, supports three single styles, crowned by stigmas. The germen afterward becomes a roundish berry, inclosing three stony seeds, which are oblong and angular on one side, but convex on the other.

This genus of plants is ranged in the twelfth section of Linnæus's twenty-second class, intitled Diœcia Monodelphia, which includes those plants which have male and female flowers in different plants, whose stamina are joined in one body.

The SPECIES are,

1. **JUNIPERUS** (*Communis*) foliis ternis patentibus mucronatis bacca longioribus. Lin. Sp. Plant. 1040. *Juniper with spreading sharp-pointed leaves placed by threes.* Juniperis vulgaris fruticosa. C. B. P. 488. *The common English Juniper.*
2. **JUNIPERIS** (*Suecia*) foliis ternis patentibus, acutiorebus, ramis erectioribus, bacca longioribus. *Juniper with longer and more acute-pointed leaves placed by threes, erect branches, and longer berries.* Juniperis vulgaris arbor. C. B. P. 488. *The Tree, or Swedish Juniper.*
3. **JUNIPERUS** (*Virginiana*) foliis ternis omnibus patentibus. *Juniper with leaves placed by threes, which are all of them spreading.* Juniperus Virginiana. H. L. Folio ubique juniperino. Boerh. Ind. *Cedar of Virginia, or red Cedar.*
4. **JUNIPERUS** (*Caroliniana*) foliis ternis basi adnatis, junioribus imbricatis, senioribus patulis. Hort. Cliff. 464. *Juniper with leaves placed by threes adbering at their base, the young ones lying over each other, and the old ones spreading.* Juniperus Virginiana, foliis inferioribus juniperinis, superioribus labinam, vel cypresum referentibus. Boerh. Ind. *Carolina Cedar.*

5. JUNI-

5. JUNIPERUS (*Bermudiana*) foliis inferioribus ternis, superioribus quadrifariam imbricatis. *Juniper with spreading under leaves placed by threes, and the upper by fours, which lie close over each other.* Juniperis Bermudiana. H. L. Cedar of Bermudas.
 6. JUNIPERIS (*Thurifera*) foliis quadrifariam imbricatis acutis. Lin. Sp. 1471. *Juniper with awl-shaped acute leaves placed by fours, lying over each other.* Juniperus major baccâ caeruleâ. C. B. P. Greater Juniper with blue berries.
 7. JUNIPERUS (*Phœnicia*) foliis ternis oblitteratis imbricatis obtusis. Lin. Sp. 1471. *Juniper with leaves placed by threes, which are obliterate, obtuse, and lying over each other.* Cedrus folio cupressi major, fructu flavescente. C. B. P. Greater Cedar with a Cypress leaf and yellowish fruit.
 8. JUNIPERUS (*Lycia*) foliis ternis undique imbricatis ovatis obtusis. Flor. Leyd. 90. *Juniper with oval blunt leaves, which every where lie over each other.* Cedrus folio cupressi media, majoribus baccis. C. B. P. 488. Middle Cedar, with a Cypress leaf and larger berries.
 9. JUNIPERUS (*Barbadensis*) foliis omnibus quadrifariam imbricatis junioribus ovatis senioribus acutis. Prod. Leyd. 90. *Juniper with all the leaves placed by fours, lying over each other, the young being oval, the older acute.* Juniperus maxima cupressi folio minimo, cortice exteriori in tenues philyras spiralis ductili. Sloan. Cat. Jam. 128. Greatest Juniper with the least Cypress leaf, and the outer bark splitting off in thin ductile pieces, commonly called Jamaica Berry-bearing Cedar.
 10. JUNIPERUS (*Sabina*) foliis oppositis erectis decurrentibus, ramis patulis. *Juniper with opposite, erect, running leaves, and spreading branches.* Sabina folio tamarisci. C. B. P. 487. Savin with a Tamarisk leaf, or common Savin.
 11. JUNIPERUS (*Lusitanica*) foliis oppositis patulis decurrentibus, ramis erectioribus. *Juniper with opposite spreading leaves, which run over each other, and more erect branches.* Sabina folio cupressi. C. B. P. 487. Savin with a Cypress leaf, commonly called Berry-bearing Savin.
 12. JUNIPERUS (*Oxycedrus*) foliis undique imbricatis obtusis, ramis teretibus. *Juniper with obtuse leaves everywhere lying over each other, and taper branches.* Juniperus major, baccâ rufescente. C. B. P. 489. Greater Juniper with a brownish berry.
 13. JUNIPERUS (*Hispanica*) foliis quadrifariam imbricatis acutis. Prod. Leyd. 90. *Juniper with acute leaves lying over each other, placed four ways.* Cedrus Hispanica procerior, fructu maximo nigro. Tourn. Inst. 588. Taller Spanish Cedar, with a very large black fruit.
- The first sort grows naturally upon chalky lands in many parts of England. This is a low shrub, seldom rising more than three feet high, sending out many spreading branches, which incline on every side, covered with a brown bark, and garnished with narrow awl-shaped leaves ending in acute points, which are placed by threes round the branches, pointing outward; these are of a grayish colour, and continue through the year; the male flowers sometimes are situated on the same plant with the female, but at distances, at other times they are upon distinct plants: the female flowers are succeeded by roundish berries, which are first green, but when ripe, are of a dark purple colour. The berries ripen in the autumn.
- The wood, the berries, and the gum, are used in medicine; the gum is titled Sandaracha.
- The second sort is known in the gardens by the title of Swedish Juniper: this is by many supposed to be only a variety of the first, but is undoubtedly a distinct species, for I have many years raised both sorts from the seeds, and have never found them alter. This sort rises to the height of ten or twelve feet, the branches grow more erect, the leaves are narrower, and end in more acute points: they are placed farther asunder on the branches, and the berries are longer. It grows naturally in Sweden, Denmark, and Norway.

The third sort grows naturally in most parts of North America, where it is called red Cedar, to distinguish it from a sort of Cypress, which is called white Cedar there. Of this there are two, if not three varieties, besides the species here enumerated; one of which has leaves in every part, like those of the Savin, and upon being rubbed, emit a very strong ungrateful odour: this is commonly distinguished in America, by the title of Savin-tree. There is another with leaves very like those of Cypress, but as these generally arise from the same seeds when they are sent from America, so they may be supposed to be only feminal variations.

The lower leaves of the fourth sort are like those of the Swedish Juniper, but the upper leaves are like those of the Cypress; and this difference is constant, if the seeds are carefully gathered from the same tree; but as most of those people who send over these seeds, are not very careful to distinguish the difference, so it often happens that the seeds of two or three sorts are mixed together, which has given occasion to people to imagine them but one species; but all the leaves of the third are like those of the Juniper, so the gardeners call this the red Virginia Cedar; and the fourth they call Carolina Cedar, though all the sorts grow naturally in Virginia.

The fifth sort is the Bermudas Cedar, whose wood has a very strong odour, and was formerly in great esteem for wainscoting of rooms, and also for furniture; but the odour being too powerful for many persons, has rendered it less valuable, and at present there is not much of it imported into England. These plants, while young, have acute-pointed leaves, which spread open, and are placed by threes round the branches; but as the trees advance, so their leaves alter, and the branches are four-cornered; the leaves are very short, and placed by fours round the branches, lying over each other like the scales of fish; the berries are produced toward the end of the branches; these are of a dark red colour, inclining to purple. As there are few of these trees of any great size in England, so I have not had an opportunity of examining their flowers, therefore do not know if they have male and female flowers on the same plant, or if they are on different plants; for although I have received very fine specimens from Bermudas, yet they are all with fruit on them almost fully grown, and not one with male flowers; and as these trees are commonly destroyed in England whenever there happens a severe winter, where they are not sheltered, so we have little hopes of seeing them in flower here.

The sixth sort grows naturally in Istria, from whence I received the berries, which have succeeded with me in the Chelsea garden. This hath spreading branches, growing thinly, which are garnished with acute-pointed leaves, placed by fours round the branches; they are of a deep green, and not very close to each other, but grow horizontally, pointing outward; the berries are much larger than those of the common Juniper, and are blue when ripe.

The seventh sort grows naturally in Portugal, from whence I have frequently received the berries. This sort grows with its branches in a pyramidical form; the lower ones are garnished with short, acute-pointed, grayish leaves, placed by threes round the branches, pointing outward; but those on the upper branches are of a dark green, lying over each other like the scales of fish, but end in acute points. The male flowers are produced at the extremity of the branches; they are situated in a loose, scaly, conical katkin, standing upon a short foot-stalk erect; the fruit is produced sometimes upon the same tree, at distances from the flowers, and at other times they are upon separate trees; the berries of this are of a pale yellow when ripe, and about the size of those of the common Juniper.

The eighth sort grows naturally in Spain and Italy, from both which countries I have received it. The branches of this sort grow erect, and are covered with a reddish brown bark; the leaves are small, obtuse, and

J U N

and lie over each other like the scales of fish; the male flowers grow at the extremity of the branches in a conical katkin, and the fruit grows single from the side of the branches below the katkins, on the same branch; the berries are large, oval, and, when ripe, are brown.

The ninth sort grows naturally in Jamaica, and also in the other islands of the West-Indies, where it rises to be one of the largest timber trees in those countries; the wood is frequently fetched from thence by the inhabitants of North America, for building of ships. This sort is generally confounded with the Bermudas Cedar, and taken for the same, but the specimens of it which were sent me by the late Dr. Houttoun, prove them to be different trees; for the branches of this spread very wide, the leaves are extremely small, and are every where lying imbricated over each other; the bark is rugged, and splits off in strings, and is of a very dark colour; the berries are smaller than those of the Bermudas Cedar, and are of a light brown colour when ripe: this sort is male and female in different trees.

The tenth sort is the common Savin; this grows naturally in Italy, Spain, and the Levant, upon the mountains where it is cold. It sends out its branches horizontally, so seldom rises more than three or four feet high, but spreads to a considerable distance every way; the branches are garnished with very short acute-pointed leaves placed opposite, which run over each other along the branches, whose ends point upward. This sort very rarely produces either flower or seed in the gardens; I have frequently examined old plants which have been standing more than fifty years, and have not more than three times found any male flowers upon them, and but once have seen any berries, which were upon a separate tree from the flowers; these berries were smaller than those of the common Juniper, but of the same colour, and were a little compressed; the whole plant has a very rank strong odour when touched. The leaves of this shrub are much used by the farriers for horses when they have worms; and Mr. Ray commends the juice of it mixed with milk, and sweetened with sugar, as an excellent medicine for children who are troubled with worms. The leaves beaten into a cataplasm with hog's-lard, will cure children's scabby heads.

The eleventh sort has, by many, been supposed to be only an accidental variety of the former, but there is a manifest difference between them; for the branches of this grow more erect than those of the eleventh sort, the leaves are shorter, and end in acute points which spread outward. This sort will rise to the height of seven or eight feet, and produces great quantities of berries. I have propagated this sort from seeds, but have never found it vary. It has been distinguished by most of the old botanists, by the title of Berry-bearing Savin. It grows naturally on the Alps, from whence I have received the berries.

The twelfth sort grows naturally in Spain, Portugal, and the south of France, where it rises ten or twelve feet high, sending out branches the whole length of the stem, which are garnished with small obtuse leaves, lying over each other like the scales of fish; the branches are small and taper, having no angles or corners, as most of the others have; the male flowers are situated at the end of the branches in conical scaly katkins, and the berries grow below from the side of the same branches. These are larger than those of the common Juniper, and when ripe are brown.

The thirteenth sort grows naturally in Spain and Portugal, where it rises from twenty-five to thirty feet high, sending out many branches which form a sort of pyramid; the branches are garnished with acute-pointed leaves, which lie over each other four ways, so as to make the branches four-cornered; the berries of this sort are very large, and black when ripe.

These plants are all propagated by sowing their seeds, the best season for which is as soon as they are ripe, if

J U N

they can then be procured; for when they are kept until spring before they are sown, they will not come up until the second year. The ground in which the seeds of the hardy sorts are sown, should be fresh and light, but it should not be dunged: it should be well dug and levelled very even; then sow your seeds thereon pretty thick, and sift some earth over them about half an inch thick; this bed will require no farther care than only to keep it clear from weeds, and toward the middle or latter end of April, you will find some of your plants appear above ground, though, perhaps, the greatest part of them may lie till the spring following before they come up; therefore you should carefully clear the beds from weeds, and in very dry weather refresh them with some water, which will greatly promote the growth of those plants which are up, and also cause the other seeds to vegetate; but if the bed in which these seeds are sown is much exposed to the sun, it should be shaded with mats in the day; for when the plants come first up, they will not bear too much heat. In this bed they should remain till the second autumn, when you must prepare some beds to transplant them into, which should also be of light, fresh, undunged soil; and having well dug and cleansed the ground from all noxious weeds and roots, you should make it level; and then in the beginning of October, which is the proper season for removing these plants, you should raise up the young plants with a trowel, preserving as much earth as possible to their roots, and plant them into beds about five or six inches asunder each way, giving them some water to settle the earth to their roots; and if it should prove very dry weather, you may lay a little mulch upon the surface of the ground round their roots, which will be of great service to the plants. But as many of the seeds will be yet left in the ground where they are sown, so the beds should not be disturbed too much in taking up the plants; for I have known a bed sown with these berries, which has supplied plants for three years drawing, some of the berries having lain so long in the ground before they sprouted; therefore the surface of the beds should be kept level, and constantly clean from weeds.

The plants may remain two years in these beds, observing to keep them clear from weeds; in the spring you should stir the ground gently between them, that their roots may with greater ease strike into it; after which time they should be transplanted, either into a nursery, at the distance of three feet row from row, and eighteen inches asunder in the rows, or into the places where they are to remain for good. The best season to transplant them (as I before observed) is in the beginning of October, when you should take them up carefully, to preserve a ball of earth to their roots; and when planted, their roots should be mulched; all which, if carefully attended to, as also observing to refresh them with water in very dry weather until they have taken new root, will preserve them from the danger of not growing; and they being extreme hardy in respect to cold, will defy the severest of our winters to injure them; provided they are not planted in a moist or rich soil.

In order to have these trees aspire in height, their under branches should be taken off, especially where they are inclined to grow strong, but they must not be kept too closely pruned, which would retard their growth; for all these Evergreen trees do more or less abound with a resinous juice, which in hot weather is very apt to flow out from such places as are wounded; so that it will not be adviseable to take off too many branches at once, which would make so many wounds, from which their sap in hot weather would flow in such plenty, as to render the trees weak and unhealthy.

The two sorts of Virginian Cedars grow to a much greater height than the former, and in their native country afford excellent timber for many uses; but with us there are very few which are above twenty-

J U N

five or thirty feet high, though there is no doubt of their growing larger; for they thrive very fast after the three first years, and resist the sharpest frost of our climate exceeding well, and are very apt to grow strait and regular, provided they are not suffered to shoot out too much at bottom.

These plants are also propagated by seeds, which must be procured from Virginia or Carolina (for they rarely produce ripe seeds in England) and sown as was directed for the other Junipers; but as this seed cannot be procured in England till spring, so when sown at that season, it remains in the ground until the succeeding spring before the plants appear; therefore you must observe to keep the beds clear from weeds, and not suffer the seeds to be disturbed, which is often the fault of some impatient people, who think, because the plants do not rise the first year, that they will never come up, and so dig up the ground again, whereby their seeds are buried; but if they are let remain, they seldom fail to grow, though sometimes it is two years after sowing before they come up. When the plants come up they must be carefully weeded, and in dry weather should be refreshed with water, which will greatly forward their growth; and the autumn following they should have a little rotten tan laid between them, to keep out the frost. In this bed the plants may remain till they have had two years growth, then they should be transplanted into other beds, as was directed before for the other sorts, observing to preserve a ball of earth to their roots; and after they are planted, if the season proves dry, they must be carefully watered, and the surface of the ground covered with mulch, to prevent the sun and wind from entering the earth to dry their fibres; but they should not be too much watered, which often proves injurious to these trees, by rotting their tender fibres soon after they are emitted, whereby the plants have been often destroyed.

In these beds they may remain two years, observing to keep them clear from weeds; and in winter you should lay a little fresh mulch upon the surface of the ground round their roots, which will prevent the frost from penetrating to them, and effectually preserve them; for while the plants are so young, they are liable to be injured by hard frosts, when too much exposed thereto; but when they have attained a greater strength, they will resist the severest of our cold.

After two years, they should either be removed into a nursery (as was directed for the common Juniper) or transplanted where they are designed to remain, observing always to take them up carefully, otherwise they are subject to fail upon transplanting; as also to mulch the ground, and water them as was before directed, until they have taken root; after which they will require no farther care, than only to keep the ground clear about their roots, and to prune up their side branches to make them aspire in height.

The soil in which you plant these trees should be fresh and light, but must not be dunged, especially at the time when they are planted; for dung is very hurtful to them, if it be not quite rotted to mould; therefore the mulch which is laid upon the surface of the ground should not be dung, but rather some old tanners bark or sea-coal ashes, which will prevent the frost from penetrating deep in the ground.

These trees being thus managed, will in a few years rise to a considerable stature, and by the variety of their evergreen leaves and manner of growth, will greatly add to the beauty of all plantations, if rightly disposed, which indeed is what we seldom observe in any of the English gardens or wildernesses; for there are few people who consider the different growths of the several trees with which they compose such plantations, so as to place the tallest growing trees the backwardest from sight, and the next degree to succeed them, and so gradually diminishing till we come to the common Juniper, and others of the same growth, whereby all the trees will be seen, and the gradual de-

J U N

clivity of their tops will appear like a verdant slope, and be much more agreeable to the sight, as also more advantageous to the growth of the trees, than to place shrubs of humble growth near such plants as will grow to the first magnitude, whereby the shrub is hid from sight, and will be over-shadowed and destroyed; nor can the distance which each tree requires, be so justly proportioned any other way; for in this distribution, the largest trees being separated by themselves, may be placed at a due distance; and then those of a middling growth succeeding, may be accordingly allowed sufficient room; and the smaller, which are next the sight, being placed much closer, will hide the naked stems of the larger trees, and have an agreeable effect to the sight.

The timber of these trees is of excellent use in America, for building of vessels, wainscoting houses, and for making many sorts of utensils, it abounding with a bitter resin, which prevents its being destroyed by vermin, but it is very brittle, therefore not so proper for stubborn uses; but however, by increasing the number of our timber trees, we shall find many advantages, besides the pleasure their variety affords; for we may hereby have trees of very different kinds, which are adapted to grow in various soils and situations, whereby we shall never want proper trees for all the different sorts of soils in England, if proper care be taken in their choice; which would be a great improvement to many parts of this kingdom, which now lie unplanted, because the owner, perhaps, find that neither Oaks nor Elms will thrive there, and consequently concludes, that no other sort of tree will, which is a great mistake; for if we consider how different the structure of trees are (being designed by the wise Author and contriver of all things, to grow on different soils and situations) and only observe what sorts are adapted for growing on dry barren mountains, and what are designed for the lower and richer valleys, we need never be at a loss for proper trees for all sorts of ground.

The Bermudas Cedar being a native of that island, and also of the Bahama Islands, is much tenderer than either of the former sorts, except that of Jamaica, so is not likely to thrive well in this country; for although many of these plants have lived several years in the open air in England, yet whenever a severe winter happens, it either kills them, or so much defaces them, that they do not recover their verdure in a year or two after.

These plants are propagated by seeds in the same manner as the former, with only this difference, that these should be sown in pots or tubs of earth, that they may be removed into shelter in the winter time, otherwise the young plants are often hurt by hard frosts; but they will require no more care than only to be placed under a common hot-bed frame, where the glasses may be constantly kept off in mild weather, when they cannot have too much free air, and only covered in hard frosts. These seeds constantly remain in the ground until the second year before they come up, therefore the earth in the pots should not be disturbed; and in the summer time they should be placed in the shade, to prevent the earth from drying too fast; and in very dry weather they should be often watered, but do not give too much water to them at once, which would rot the seeds.

The spring following, when the young plants come up, they must be carefully cleared from weeds, and in dry weather refreshed with water; but should stand, during the summer season, in a place defended from strong winds; and in winter must be placed under frames, where they may be covered in hard frosty weather, but must have open air when the weather is mild. In April following you should transplant them each into a single halfpenny pot filled with fresh light earth, being careful to raise them up with a ball of earth to their roots; and when they are planted, you should water them, to settle the earth to their roots; then place the pots in a warm situation, where they may be defended from sun and wind: but if you will bestow a moderate hot bed to plunge the pots in, it will

J U N

will greatly promote their taking new root; however, you must carefully defend them from the great heat of the sun, which is injurious to them when fresh removed; but when they have taken root, you may expose them by degrees to the open air. If you suffer the pots to remain plunged all the summer, it will preserve the earth therein from drying so fast as it would do, if they were set upon the ground.

In October you should again remove these plants into shelter, or else plunge their pots into the ground under a warm hedge, where they may be protected from the cold north and east winds; and in the spring following you must shift the plants into pots a size larger, taking away some of the earth from the outside of the ball, and adding some fresh, which will promote their growth; and so continue to manage them as was before directed, until you plant them out in the places where they are designed to remain; which should not be done till they are four or five years old, by which time they will be strong enough to bear the cold of our common winters.

The reason for my directing these plants to be preserved in pots until they are planted out for good is, because they are difficult to transplant, and being tender will require some shelter while young; and whoever observes the method here laid down, will find the plants so managed to gain two years growth in six, from those raised in the open air, and be in less danger of being destroyed; and as the trouble and expence in raising them this way is not great, so it is worth practising, since in a few years the trees will recompense the trouble.

The timber of this tree is of a reddish colour, and very sweet, and is commonly known in England by the name of Cedar Wood; though there are divers sorts of wood called by that name, which come from very different trees, especially in the West-Indies, where there are several trees of vastly different appearances and genera, which have that appellation: it is this wood which is used for pencils, as also to wainscot rooms, and make stair-cases, it enduring longer sound than most other sorts of timber, which, perhaps, may be owing to some extreme bitter taste in the resin, with which the tree abounds; for it is very remarkable, that the worms do not eat the bottoms of the vessels built with this wood, as they do those built with Oak; so that the vessels built with Cedar are much preferable to those built with any other sort of timber, for the use of the West-India seas, but they are not fit for ships of war, the wood being so brittle as to split to pieces with a cannon ball.

The Jamaica Juniper is more impatient of cold than the Bermudas, so will not live through the winter in the open air in England, and the plants must be preserved in pots and housed in the winter; this is propagated by seeds, in the same way as the Bermudas Cedar; but if the pots are plunged into a moderate hot-bed the second spring after the seeds are sown, it will bring up the plants sooner, and they will have more time to get strength before winter.

All the other sorts are hardy enough to live in the open air, so are very well worth propagating, as they will add to the variety of Evergreen plantations; some of the sorts will rise to a very considerable height, so may prove to be useful timber, and may be adapted to such soils as will not suit many other trees.

The common Savin should not be neglected, because it is so very hardy as never to be injured by the severest frost; and as this spreads its branches near the ground, so if the plants are placed on the borders of woods, they will have a good effect in winter, by screening the nakedness of the ground from sight.

All these sorts are propagated by their seeds, which may be sown in the same way as the common Juniper, and the plants afterward so managed; and most of the sorts may be propagated by cuttings, which, if planted in autumn in a shady border will take root; but those plants which are raised from cuttings will never grow so upright, nor to so large a size as the plants

J U N

which are raised from seeds; so that when these can be procured, it is much the better method, but the other is frequently practised on those sorts which do not perfect their seeds in England.

As several of these sorts grow to the height of eighteen or twenty feet, the procuring as many of the sorts as can be gotten from the countries of their growth, will be adding to the variety of our Evergreen plantations, which cannot be too much propagated in England, where, in general, our winters are temperate enough for them to thrive to advantage; and as the sorts which are a little more tender than the others obtain strength, they will be in less danger of suffering by severe winters, as we find by many other plants, which were so tender as not to live in the open air at first, but now defy the severest cold of our climate.

JUSSIAEA. Lin. Gen. Plant. 478.

The CHARACTERS are,

It hath a small permanent empalement, divided into five segments at the top, sitting upon the germen. The flower has five roundish spreading petals, and ten short slender stamina, terminated by roundish summits. The oblong germen supports a slender style, crowned by a flat stigma, marked with five stripes. The germen afterward becomes a thick oblong capsule, crowned by the empalement, which opens lengthways, and is filled with small seeds.

This genus of plants is ranged in the first section of Linnaeus's tenth class, intitled Decandria Monogynia, which includes the plants whose flowers have ten stamina and one style.

The SPECIES are,

1. **JUSSIAEA** (*Suffruticosa*) erecta villosa, floribus tetrapetalis, decandris sessilibus. Lin. Sp. Plant. 555. *Upright hairy Jussiaea, with flowers sitting close to the stalks, having four petals and ten stamina. Lyfimachia Indica non papposa, flore luteo minimo, siliquis caryophyllum aromaticum æmulantibus. H. L. 396. Indian Primrose with a very small yellow flower, and pods resembling Cloves.*
2. **JUSSIAEA** (*Pubescens*) villosa, caule erecto ramoso, floribus pentapetalis, decandris sessilibus. *Hairy Jussiaea with an erect branching stalk, flowers having five petals, and ten stamina which sit close to the stalk. Lyfimachia lutea erecta, non papposa major, foliis hirsutis, fructu caryophylloide. Sloan. Cat. Jam. 85. Yellow upright larger Tree-Primrose with hairy leaves, and a fruit like Cloves.*
3. **JUSSIAEA** (*Erecta*) erecta glabra, floribus tetrapetalis octandris sessilibus. Flor. Zeyl. 170. *Smooth upright Jussiaea with four petals, and eight stamina to the flowers, which sit close to the stalk. Lyfimachia lutea non papposa, erecta, foliis glabris, fructu caryophylloide. Sloan. Cat. Jam. 85. Yellow upright Tree-Primrose with smooth leaves, and a fruit like Cloves.*
4. **JUSSIAEA** (*Onagra*) caule erecta ramoso glabro, floribus tetrapetalis octandris sessilibus, foliis lanceolatis. *Jussiaea with an upright, branching, smooth stalk, flowers having four petals, and eight stamina sitting close to the stalk, and spear-shaped leaves. Onagra foliis persicariæ amplioribus, parvo flore luteo. Plum. Cat. 7. Tree-Primrose with a large Arsesmart leaf, and a small yellow flower.*
5. **JUSSIAEA** (*Hirsuta*) caule erecto simplici hirsuto, foliis lanceolatis, floribus pentapetalis decandris sessilibus. *Jussiaea with a single, upright, hairy stalk, spear-shaped leaves, and flowers which have five petals, and ten stamina sitting close to the stalk. Onagra erecta, caule rubro hirsuto, foliis oblongis, flore magno luteo. Houst. MSS. Upright Primrose with a hairy leaf of a reddish colour, oblong leaves, and a large yellow flower.*

The first sort grows naturally at Campeachy, from whence the seeds were sent me by the late Mr. Robert Millar; this rises with a shrubby stalk near three feet high, sending out several side branches, which are garnished with oblong hairy leaves placed alternate. The flowers come out from the side of the stalks singly, having short foot-stalks; they have four small yellow petals with eight stamina; these sit upon the germen, which afterward becomes an oblong seed-vessel, crowned by the four-leaved empalement, and has a great resemblance

semblance to Cloves. This plant flowers in July and August, and the seeds ripen in October.

The second sort grows naturally in Jamaica. The seeds of this were sent me by the late Dr. Houstoun; this rises with a hairy branching stalk two feet high, and is garnished with narrow spear-shaped leaves, placed alternate. The flowers come out toward the end of the branches singly from the wings of the leaves, sitting close to the stalk; they are composed of five pretty large yellow petals, and ten stamina; these sit upon a long germen, which afterward becomes the seed-vessel, crowned by the empalement; these are filled with small seeds. It flowers and seeds about the same time with the last.

The third sort grows naturally in Jamaica, from whence the seeds were sent me with those of the former sort; this rises with a smooth erect stalk three feet high, garnished with long, narrow, smooth, spear-shaped leaves. The flowers are large and yellow, sitting close to the stalk; these are succeeded by long seed-vessels, shaped like those of the other sorts. It flowers and seeds at the same time with the former.

The fourth sort was sent me from Carthage by the late Dr. Houstoun; this hath a branching smooth stalk near three feet high, garnished with spear-shaped leaves, standing upon short foot-stalks. The flowers are small, yellow, and are composed of four petals and eight stamina; these sit very close to the stalk, and are succeeded by seed-vessels, shaped like those of the former sorts.

The fifth sort was sent me from La Vera Cruz, by the late Dr. Houstoun; this rises with single upright red stalks three feet high, which are hairy and channelled. The leaves are spear-shaped, and placed alternate on the stalks, standing nearer together than in any of the other sorts. The flowers come out from the wings of the leaves, toward the top of the stalk; they are composed of five large yellow petals, and ten stamina sitting close to the stalks, and are succeeded by seed-vessels which are one inch long, and shaped like those of the former sorts.

The first, second, and fourth sorts are annual plants, at least they are so in England; for if the plants are raised early in the spring, they will flower in July, and ripen their seed the beginning of October; and those plants which are raised later in the spring, cannot be preserved through the winter, though they are placed in a warm stove; nor do their stalks ever grow ligneous, or shew any signs of their being perennial in their native country.

The third and fifth sorts have continued through the winter in the bark-stove, but those have been such plants as did not flower and seed the first year; for after they had perfected seeds, the following summer the plants decayed.

All these sorts are propagated by seeds, which should be sown early in the spring, in pots filled with a soft loamy soil, and plunged into a moderate hot-bed; but as these seeds often lie a whole year in the ground before they vegetate, the earth must be kept moist, and the glasses of the hot-bed shaded in the heat of the day, by this method the seeds may be brought soon to vegetate; when the plants come up, and are fit to remove, they should be each planted into a small separate pot, filled with light loamy earth, and plunged into a hot-bed of tanners bark, where they should be shaded from the sun till they have taken new root; after which they should have free air admitted to them every day, in proportion to the warmth of the season; they must also be frequently refreshed with water, but it must not be given to them in too great plenty: when the roots of the plants have filled these small pots, the plants should be removed into others a size larger; and if the plants are too tall to stand under the frames of the hot-bed, they should be removed into the bark-stove, where they may remain to flower and perfect their seeds; for when the plants rise early in the spring, and are brought forward in hot-beds, all the sorts will flower and perfect their

seeds the same year, which is better than to have them to keep through the winter.

JUSTICIA. Houst. Nov. Gen. Lin. Gen. Plant. 27. Adhatoda. Tourn. Inst. R. H. 175. tab. 79. This plant was so named by the late Dr. Houstoun, in honour of James Justice, Esq; a great lover and encourager of gardening and botany.

The CHARACTERS are;

The empalement of the flower is small, and divided into five acute segments at the top. The flower hath one petal, which is divided into two lips almost to the bottom, which are entire. The upper lip is raised archways, and the under is reflexed. It hath two awl-shaped stamina situated under the upper lip, terminated by erect summits which are bifid at their base. It hath an oblong germen, supporting a slender style which is longer than the petal, crowned by a single stigma. The germen afterward becomes an oblong capsule with two cells, divided by a partition, which is contrary to the two valves, which open with an elasticity, and cast out the roundish seeds.

This genus of plants is ranged in the first section of Linnæus's second class, intitled Diandria Monogynia, which includes those plants whose flowers have two stamina and one style. To this genus of Dr. Houstoun's is joined the Adhatoda of Tournefort, but there is a distinction in their flowers; the two lips of Justicia are entire, but the upper lip of Adhatoda is indented at the end, and the under is divided into three parts; and in the capsule of Justicia there are seldom more than two seeds, but in Adhatoda several.

The SPECIES are,

1. **JUSTICIA** (*Scorpioides*) foliis oblongo-ovatis hirsutis, sessilibus, floribus spicatis alaribus, caule fruticoso. *Justicia with oblong, oval, hairy leaves sitting close to the stalks, and flowers growing in spikes proceeding from the side of the stalks, which are shrubby. Justicia frutescens, floribus spicatis majoribus, uno versu dispositis.* Houst. MSS. *Shrubby Justicia with larger flowers growing in spikes, which are ranged on one side.*
2. **JUSTICIA** (*Sexangularis*) caule erecto ramoso hexangulati, foliis ovatis oppositis, bracteis cuneiformibus confertis. *Justicia with an erect branching stalk, having six angles, oval leaves placed opposite, and wedge-shaped small leaves (or bractes) growing in clusters. Justicia annua hexangulati caule, foliis Circæe conjugatis, flore miniato.* Houst. MSS. *Annual Justicia with an hexangular stalk, Eucharis Nightshade leaves set by pairs, and a carmine flower.*
3. **JUSTICIA** (*Fruticosa*) foliis ovato-lanceolatis, pediculis hirsutis, bracteis cordatis acuminatis, caule fruticoso. *Justicia with oval spear-shaped leaves growing on foot-stalks, heart-shaped acute-pointed bractes, and a shrubby stalk. Justicia frutescens & hirsuta, foliis oblongis pediculis longissimis, flore rubro.* Houst. MSS. *Shrubby and hairy Justicia with oblong leaves growing on very long foot-stalks, and a red flower.*
4. **JUSTICIA** (*Adhatoda*) arborea, foliis lanceolato-ovatis, bracteis ovatis persistentibus, corollarum galea concava. Flor. Zeyl. 16. *Tree-Justicia with oval spear-shaped leaves, oval permanent bractes, and a concave helmet to the flower. Adhatoda Zeylanensium.* H. L. 642. *Adhatoda of Ceylon, commonly called Malabar Nut.*
5. **JUSTICIA** (*Hyssopifolia*) fruticosa, foliis lanceolatis integerrimis, pedunculis trifloris ancipitibus, bracteis calyce brevioribus. Lin. Sp. Plant. 15. *Shrubby Justicia with entire spear-shaped leaves, foot-stalks having three flowers placed different ways, and a bractea shorter than the empalement. Adhatoda Indica, folio saligno, flore albo.* Boerh. Ind. alt. 1. 239. *Indian Adhatoda with a Willow leaf and white flower, commonly called Snap-tree.*
6. **JUSTICIA** (*Spinosa*) spinosa, foliis oblongo-ovatis emarginatis, caule fruticoso ramoso. *Prickly Justicia with oblong oval leaves indented at their edges, and a shrubby branching stalk. Adhatoda Antegoana, Lycii facie, spinosa.* Petiv. *Prickly Adhatoda of Antigua, with the appearance of Boxthorn.*

woolly on their under side, sitting close to the stalks, with spikes of flowers growing in clusters at the ends of the branches. *Adhatoda arborea*, foliis oblongis, subtus villosis, floribus spicatis albis. Houst. *Tree-Adhatoda* with oblong leaves, hairy on their under side, and spikes of white flowers.

8. *JUSTICIA (Ecbolium)* arborea, foliis lanceolato ovatis, bracteis ovatis deciduis mucronatis, corollarum galeâ reflexâ. Flor. Zeyl. 17. *Trec-Justicia* with spear-shaped oval leaves, oval-pointed bractæ which fall off, and a reflexed helmet to the flowers. *Adhatoda spica longissima*, flore reflexo. Burman. Zeyl. 7. tab. 4. f. 1. *Adhatoda* with a very long spike, and a reflexed flower.

The first sort was discovered growing naturally at La Vera Cruz, by the late Dr. Houstoun, who sent the seeds to England; this rises with a shrubby brittle stalk five or six feet high, sending out many branches, which are garnished with oblong oval leaves, two inches long, and one inch broad, which are hairy and placed opposite; from the wings of the leaves come out the spikes of flowers, which are reflexed like a scorpion's tail. The flowers are large, of a carmine colour, and ranged on one side of the spike; these are succeeded by short pods about half an inch long.

The second sort was discovered by the same gentleman, in the same country; this is an annual plant with an upright stalk, having six angles, which rises two or three feet high, dividing into many branches, garnished with oval leaves placed opposite, an inch and a half long, and one inch broad; they are smooth, as are also the stalks. At each joint come out clusters of small wedge-shaped leaves, which are by Dr. Linnaeus termed bractæ, and long before the stalks decay, most of the larger leaves fall off, so there are only these small leaves remaining. The flowers are produced in small spikes at the side of the branches, sitting very close among the leaves; they are of a beautiful carmine colour, and have but one petal, which has two lips. The upper lip is arched, bending over the lower, which is also a little reflexed, but both are entire. The flowers are succeeded by short wedge-shaped capsules, opening lengthways, inclosing two small oval seeds.

The third sort was discovered by the same gentleman at Campeachy; this rises with a hairy shrubby stalk four or five feet high, dividing into several branches, garnished with oval, spear-shaped, hairy leaves, four inches long, and two inches and a half broad, standing upon foot-stalks which are above an inch long, placed opposite. At the base of the foot-stalks come out a cluster of small heart-shaped leaves, ending in acute points, which are termed bractæ. The flowers come out in loose clusters from the wings of the stalks, toward the end of the branches; they are of a pale red colour, and shaped like those of the former sort.

These plants are propagated by seeds, which should be sown early in the spring, in small pots filled with fresh light earth, and plunged into a moderate hot-bed of tanners bark, observing to water the earth gently as it appears dry. The seeds of these plants frequently lie a year in the ground, so that the pots must not be disturbed, if the plants do not come up the same year; but in the winter should be kept in the stove, and the spring following plunged into a fresh hot-bed, which will bring up the plants if the seeds were good. When the plants begin to appear, the glasses of the hot-bed should be raised every day, when the weather is warm, to admit fresh air to them. The plants must also be frequently watered in warm weather; but water should not be given in large quantities while the plants are young, because they are then very tender, and subject to rot at the bottom of their stems, with much moisture.

When the plants are about two inches high, they should be carefully taken up, and each transplanted into a separate small pot filled with fresh light earth, and then plunged into the hot-bed again, being careful to water and shade them until they have taken new root; after which time they should have air admitted to them every day, in proportion to the warmth of

the season, and should be duly watered every two or three days in hot weather.

As the plants advance in their growth, they should be shifted into larger pots, for if their roots are too much confined, the plants will not make any considerable progress; but they should not be over potted, for that will be of worse consequence than the other; because when they are planted in very large pots, they will starve and decay, without producing any flowers. They are too tender to endure the open air in this country, therefore they should always remain in the hot-bed, being careful to let them have a due proportion of air in hot weather; and the annual sort should be brought forward as fast as possible in the spring, that the plants may flower early, otherwise they will not produce good seeds in England.

The first and third sorts should remain in the hot-bed during the summer season (provided there is room under the glasses, without being scorched;,) but at Michaelmas they should be removed into the stove, and plunged into the bark-bed, where they must remain during the winter season, observing to keep them warm, as also to water them gently once or twice a week, according as they shall require. The following summer these plants will flower, and abide several years, but they rarely produce good seeds in Europe. The fourth sort grows naturally in the island of Ceylon, but has been long in the English gardens, where it is commonly known at present by the title of Malabar Nut; but was formerly called Beetle Nut, and was by some supposed to be the tree of which the Chinese chew the leaves and nuts: this, though a native of so warm a country, is hardy enough to live in a good green-house in England, without any artificial heat. It rises here with a strong woody stalk to the height of twelve or fourteen feet, sending out many spreading branches, which are garnished with spear-shaped oval leaves more than six inches long, and three inches broad, placed opposite. The flowers are produced on short spikes at the end of the branches, which are white, with some dark spots; these appear in July, but are not succeeded by any seeds in England.

This sort may be propagated by cuttings, which, if planted in pots in June or July, and plunged into a very moderate hot-bed, will take root; but they must be every day screened from the sun, and if the external air is excluded from them, they will succeed better than when it is admitted to them. It may also be propagated by laying down their young branches, which will take root in the tubs or pots in one year; then the young plants should be put each into a separate pot, filled with soft loamy earth, and placed in the shade till they have taken new root, when they may be placed in a sheltered situation during the summer, but in winter they must be housed, and treated in the same way as Orange-trees, with only this difference, that these require more water.

The fifth sort grows naturally in India; this rises with a shrubby stalk from three to four feet high, sending out branches on every side from the bottom, so as to form a kind of pyramid; these are covered with a white bark, and garnished with spear-shaped entire leaves, near two inches long, and one third of an inch broad; they are smooth, stiff, and of a deep green, standing opposite. At the base of the foot-stalks come out clusters of smaller leaves, of the same shape and texture. The flowers come out upon short foot-stalks from the side of the branches, each foot-stalk supporting one or two white flowers, having long empalements; these are succeeded by oblong seed-vessels, which, when ripe, cast out their seeds with an elasticity, from whence it had the title of Snap-tree.

This is propagated by cuttings during any of the summer months; they should be planted in pots filled with light loamy earth, and plunged into a moderate hot-bed, and shaded from the sun, and now and then gently refreshed with water, and not too much air admitted to them. In about two months the cuttings will have taken root, then they must be gradually

inured to bear the open air, into which they should be removed, placing them in a sheltered situation, where they may stay till autumn; but if they get root pretty early in the summer, it will be proper to separate them each into a single small pot, setting them in the shade till they have taken new root, after which they may be placed as before directed; but when it is late in the season before they take root, it will be better to let them remain in the same pots till the following spring. In winter these plants must be placed in a warm green-house, or in a moderately warm stove, for they are impatient of cold and damp, nor will they thrive in too much warmth; they will often require water in winter, but during that season it must be given them moderately; in summer they must be removed into the open air, but should have a warm sheltered situation, and in warm weather they must have plenty of water. This plant flowers at different seasons, but never produces fruit here.

The sixth sort grows naturally in Jamaica, from whence the late Dr. Houstoun sent it to England; this rises with many shrubby slender stalks about five feet high, sending out branches on every side from the root upward, which grow erect, and are covered with a whitish bark, garnished with small, oblong, oval leaves, coming out on each side the stalk opposite, and under the leaves are placed at every joint two sharp thorns like those of the Berberry; the flowers come out singly from the wings of the leaves, they are small, and of a pale red colour, shaped like those of the other sorts.

The seventh sort was found by the late Dr. Houstoun, growing naturally at Campeachy. This rises with a strong woody stem twenty feet high, dividing into many crooked irregular branches, covered with a light brown bark, garnished with spear-shaped oval leaves, near four inches long and two broad, which are covered with a soft down on their under side. The flowers grow in spikes from the end of the branches, three, four, or five of these spikes arising from the same point, the middle spike being near three inches long, and the others about half that length. The flowers are small and white, but shaped like those of the other species.

The eighth sort grows naturally at Malabar and in Ceylon; this rises in its native soil with a strong woody stem ten or twelve feet high, dividing into many branches, which are garnished with spear-shaped oval leaves five inches long, and two and a half broad, of a lucid green, placed opposite. The flowers grow in very long spikes from the end of the branches, they are of a greenish colour with a shade of blue; the helmet of the flower is reflexed.

These three sorts are propagated by seeds in the same manner as the three first, and the plants must be treated in the same way, especially while they are young; but afterward the eighth sort may be more hardly treated, when they have gotten strength. This sort may also be propagated by cuttings, in the same manner as the fifth sort; and when the plants are two or three years old, they will thrive in a moderate degree of warmth in winter, and in the summer they may be placed abroad for two months in the warmest season of the year; but they should have a warm sheltered situation, and when the nights begin to grow cold, they must be removed into the stove, but they must have free air admitted to them at all times when the weather is warm. The other two sorts should constantly remain in the bark-stove, and require the same treatment as other tender plants from the warmest countries.

IXIA. Lin. Gen. Plant. 54. Sisyrrinchium. Com. Hort. Amst.

The CHARACTERS are,

It hath oblong permanent spathe (or sheaths) which inclose the germen; the flower has six oblong spear-shaped petals which are equal, and three awl-shaped stamina which are shorter than the petals, situated at equal distances, terminated by single summits. It hath an oval three-cornered germen situated below the flower, supporting a single style

which is the length of the stamina, crowned by a thick trifid stigma; the germen afterward becomes an oval three-cornered capsule with three cells, filled with roundish seeds.

This genus of plants is ranged in the first section of Linnæus's third class, intitled Triandria Monogynia, which includes those plants whose flowers have three stamina and one style.

The SPECIES are,

1. **IXIA** (*Chinensis*) foliis ensiformibus, floribus remotis panicula dichotoma, floribus pedunculatis. Hort. Upsal. 16. *Ixia with sword-shaped leaves, and flowers standing remote in forked panicles upon foot-stalks.* Bermudiana iridis folio majori flore croceo, eleganter punctato. Kraus. Hort. 25. tab. 25. *Bermudiana with a larger Iris leaf, and a Saffren-coloured flower, which is beautifully spotted.*
2. **IXIA** (*Africana*) floribus capitatis, spathis laceris. Lin. Sp. Plant. 36. *Ixia with flowers growing in heads, having ragged sheaths.* Bermudiana Capensis, capitulis lanuginosis. Pet. Hort. Sicc. 242. *Bermudiana from the Cape of Good Hope, with woolly heads.*
3. **IXIA** (*Scillaris*) foliis gladiolatis, nervosis, hirsutis, floribus spicatis terminalibus. Icon. tab. 155. fig. 1. *Ixia with sword-shaped, hairy, veined leaves, and flowers growing in spikes at the ends of the stalks.*
4. **IXIA** (*Polystachia*) foliis lineari-gladiolatis, floribus alaribus & terminalibus. Icon. tab. 155. fig. 2. *Ixia with narrow sword-shaped leaves, and flowers proceeding from the sides and tops of the stalk.*
5. **IXIA** (*Crocata*) foliis gladiolatis glabris, floribus corymbosis terminalibus. Icon. tab. 156. *Ixia with smooth spear-shaped leaves, and flowers growing in a corymbus terminating the stalk.* Sisyrrinchium Africanum majus, flore luteo maculâ notato. Olden. *Greater African Sisyrrinchium with a yellow spotted flower.*
6. **IXIA** (*Bulbifera*) foliis lineari-gladiolatis, floribus alternis, caule bulbifero. *Ixia with narrow sword-shaped leaves, flowers placed alternate, and stalks bearing bulbs.*
7. **IXIA** (*Sparsa*) foliis gladiolatis, floribus distantibus. *Ixia with sword-shaped leaves, and flowers growing distant.*
8. **IXIA** (*Flexuosa*) foliis lineari-gladiolatis, floribus spicatis sessilibus terminalibus. *Ixia with narrow sword-shaped leaves, and sessile flowers growing in spikes at the top of the stalk.*

The first sort grows naturally in India, where the stalks rise to the height of five or six feet, but in England they are seldom more than half that height. It hath a pretty thick fleshy root, divided in knots or joints of a yellowish colour, sending out many fibres; the stalk is pretty thick, smooth, and jointed, garnished with sword-shaped leaves a foot long and one inch broad, with several longitudinal furrows embracing the stalks with their base, ending in acute points; the upper part of the stalk divaricates into two smaller, with a foot-stalk arising between them, which supports one flower; the smaller branches divaricate again in the same manner into foot-stalks, which are two inches long, each sustaining one flower. At each of these joints is a spatha or sheath embracing the stalk, which at the lower joints are three inches long, but the upper are not more than one inch, ending in acute points which are permanent; the flowers are composed of six equal petals, of a yellow colour within, and variegated with dark red spots; the outside is of an Orange colour. These appear in July and August, and in warm seasons are succeeded by seeds.

This sort may be propagated either by seeds or parting of the roots: if by seeds they should be sown in pots, and plunged into a moderate hot-bed, which will bring up the plants much sooner than when they are sown in the full ground; when the plants are fit to remove, they should be each planted in a small separate pot filled with light earth, and if they are placed under a frame till they have taken good root in the pots, it will greatly forward their growth; afterward they may be placed in the open air in a sheltered situation, where they may remain till the autumn, when they

I X I

they must be placed under a frame to screen them from frost; and in the spring most of the plants may be turned out of the pots and planted in a warm border, where they will abide through the common winters very well, but in severe frosts they are often killed, unless they are covered with tan, or other covering to keep out the frost; therefore a few of the plants may be kept in pots; and sheltered under a frame in winter.

The stalks and leaves of this plant decay to the root in autumn, so that if the surface of the ground about the roots is covered two or three inches thick with tan, it will secure them from the danger of frost; and in the spring, before the roots shoot, will be the best time to remove and part the roots; but this should not be done oftener than every third year, for when they are often parted they will be weak, and will not flower so well.

The second sort grows naturally at the Cape of Good Hope; this is a low plant, which rarely rises more than three or four inches high; the leaves are narrow and veined, the flowers are small, growing in a downy head on the top of the stalk, but they make little appearance, so are only kept for the sake of variety.

The third sort I raised from seeds, which were sent me from the Cape of Good Hope. This hath a round bulbous root a little compressed, covered with a red skin, from which arise five or six sword-shaped leaves about three or four inches long, hairy, and with several longitudinal furrows; these embrace each other at their base, but spread asunder at the top; between these come out the flower-stalk, which rises six or eight inches high, is naked to the top, and terminated by a cluster of flowers, each having a spatha or hood, which dries and is permanent; the flowers are of a deep blue colour, and appear in May; these are succeeded by roundish three-cornered seed-vessels with three cells, filled with roundish seeds which ripen in July, then the leaves and stalks decay.

The fourth sort was raised from seeds in the Chelsea garden, which came with those of the former sort. This hath a small round bulbous root, from which arise four or five narrow, long, sword-shaped leaves, six or seven inches long; between these come out a very slender round stalk about ten inches long, from the side of which there comes out one or two clusters of flowers, standing upon short foot-stalks, and at the top of the stalk the flowers grow in a loose spike; they are of a pure white, and shaped like those of the other species. These appear in May, and the seeds ripen in July.

The seeds of the fifth sort were sent me from the Cape of Good Hope; this has an oval bulbous root which is a little compressed, from which come up three or four narrow, thin, sword-shaped leaves, near a foot long; the flower-stalk rises a little above the leaves, it is very slender, naked, and terminated by a round cluster of flowers, each having a spatha or hood; they are composed of six pretty large oblong petals which are concave, and of a deep yellow colour, each having a large black spot at the base. This flowers early in May, and the seeds ripen the latter end of June.

The sixth sort hath narrow spear-shaped leaves about six or seven inches long; the stalk rises near a foot and a half high, garnished with one leaf at each of the lower joints, of the same shape with the other, but smaller; these embrace the stalk with their base, and stand erect; the upper part of the stalk is adorned with flowers, composed of six oblong oval petals of a sulphur-colour, which are placed alternate on the stalk, which is bent at each joint where the flowers stand; the flowers have three short stamina which are joined at their base, terminated by long, flat, erect summits; the germen is situated under the flower, supporting a long slender style, crowned by a trifid stigma; the germen afterward becomes a roundish capsule with three cells, filled with roundish small seeds. The stalks at each of the lower joints thrust out small

I X O

bulbs, which, if planted, will grow and produce flowers.

The seventh sort hath shorter and broader leaves than the former; the stalk is slender and furrowed; and at each of the lower joints is garnished with one leaf of the same shape, embracing the stalk with their base; the flowers come out toward the top of the stalk, at two or three inches distance, each stalk supporting two or three sulphur-coloured flowers; which are each composed of six spear-shaped petals an inch and a half long, equal in their size and regular in position; they have a short permanent empalement, cut into two long and two shorter acute segments; these are succeeded by round capsules with three cells, filled with round seeds. This sort flowers in March, and the seeds ripen about two months after.

The eighth sort hath very small, round, bulbous roots, from which arise three or four long, slender, Grass-like leaves, of a dark green colour; between these come out the stalk, which is very slender and round, rising a foot and a half high; at the top the flowers are collected in a spike sitting close to the stalk, each having a thin, dry, permanent spatha or sheath, which covers the capsule after the flower is fallen. The flowers are of a pure white, and shaped like those of the other species, but are smaller; they are succeeded by small round seed-vessels with three cells, each containing two or three round seeds. It flowers the latter end of May, and the seeds ripen in July.

There are some other varieties of this genus, which have flowered in the Chelsea garden, differing only in the colour of their flowers, so are not supposed to be distinct species; one of which is purple on the outside, and white within; another has white flowers, with a blue stripe on the outside of each petal, and a third has white flowers with yellow bottoms. These have already flowered in the Chelsea garden, where there are many more, which have been since raised from seeds, whose flowers have not as yet appeared; and at the Cape of Good Hope, where these plants grow naturally, there are more than thirty varieties mentioned in a catalogue of Dr. Herman's. The roots of most, if not all these sorts, are frequently eaten by the inhabitants at the Cape of Good Hope, who greatly esteem them.

All the sorts multiply very fast by offsets, so that when once obtained, there will be no occasion to raise them from seeds; for the roots put out offsets in great plenty, most of which will flower the following season, whereas those from seeds are three or four years before they flower. These plants will not live through the winter in the full ground in England, so should be planted in small pots filled with light earth, and placed under a frame in winter, where they may be protected from frost, but in mild weather should enjoy the free air; but during the winter they must be guarded from mice, who are very fond of these roots, and if not prevented will devour them.

I X O R A. Lin. Gen. 131. *Jasminum*. Burman.

The CHARACTERS are,

It hath a small permanent empalement cut into four segments; the flower has one funnel-shaped petal, having a slender tube, cut into four segments at the top. It hath four short stamina situated in the divisions of the petal, terminated by oblong summits, and a roundish germen situated at the bottom of the involucre, supporting a slender style the length of the tube, crowned by a bifid stigma; the germen afterward becomes a berry with two cells; containing two convex angular seeds.

This genus of plants is ranged in the first order of Linnæus's fourth class, intitled Tetrandria Monogynia, the flowers having four stamina and one style.

The SPECIES are,

1. *IXORA* (Coccinea) foliis ovatis semiamplexicaulibus, floribus fasciculatis. Flor. Zeyl. 22. *Ixora* with oval leaves half embracing the stalks, and flowers growing in bunches. *Jasminum Indicum lauri folio, inodorum umbellatum, floribus coccineis.* Pluk. Phyt. tab. 59. f. 2.

I X O

IXORA (*Alba*) foliis ovato-lanceolatis, floribus fasciculatis. Lin. Sp. 160. *Ixora with oval spear-shaped leaves, and flowers growing in bunches.* Jasminum Indicum, lauri folio, inodorum, floribus albicantibus & schetti album. Pluk. Phyt. 109. f. 2.

3. **IXORA** (*Americana*) foliis ternis lanceolato-ovatis, floribus thyrsoides. Amœn. Acad. 5. p. 393. *Ixora with oval spear-shaped leaves placed by threes, and flowers in a loose spike.* Pavetta foliis oblongo-ovatis oppositis, stipulis setaceis. Brown. Jam. tab. 6. f. 2.

The first sort grows naturally in India, where it rises with a woody stalk five or six feet high, sending out many slender branches covered with a brown bark, garnished with oval leaves, placed sometimes opposite, and at others there are three or four at each joint. The flowers terminate the branches in clusters; they have very long slender tubes, are cut into four oval segments at the top, and are of a deep red colour.

The second sort grows also in India; this hath a woody stalk rising six or seven feet high, sending out weak branches, garnished with oval spear-shaped leaves placed opposite, sitting close to the branch; the flowers terminate the branches in small clusters; they have long slender tubes, divided into four segments at the top, and are white, without scent.

The third sort grows naturally in Jamaica, and some other islands in the West-Indies, where it is called Wild Jasmine. This rises with a shrubby stalk four or five feet high, sending out slender branches opposite, which are garnished with oval spear-shaped leaves placed opposite, which are six inches long, and

I X O

two inches and a half broad, having short foot-stalks; the flowers are produced at the end of the branches in a loose spike, they are white, and have a scent like Jasmine.

These plants are propagated by seeds, when they can be procured from the countries where they grow naturally, for they do not perfect any seeds in England. They should be sown in small pots as soon as they arrive, and plunged into a hot-bed; if they arrive in autumn or winter, the pots may be plunged in the tan-bed in the stove, between the other pots of plants, so will take up little room; but when they arrive in the spring, it will be best to plunge them in a tan-bed under frames; the seeds will sometimes come up in about six weeks, if they are quite fresh; otherwise they will lie in the ground four or five months, and sometimes a whole year, therefore the earth should not be thrown out of the pots till there is no hopes of their growing; when the plants come up, and are fit to remove, they should be each planted in a separate small pot, filled with light earth, and afterward treated in the manner directed for the Coffee-tree.

They may also be increased by cuttings during the summer months, and planted in small pots plunged into a moderate hot-bed, covering them close either with bell or hand-glasses to exclude the external air, shading them carefully from the sun during the heat of the day, until they have put out good roots, when they should be parted, and each put into a separate pot, treating them as the seedling plants.

K A L

K A L I. See SALSOLA.
KALMIA. Lin. Gen. Plant. 482. Chamærhododendros. Tourn. Inst. R. H. 604. tab. 373.

The CHARACTERS are,

The flower has a small permanent empalement cut into five parts, and one petal cut into five segments, which spread open and are roundish. It hath ten stamina the length of the petal, which decline in the middle, terminated by oval summits. In the center is situated a roundish germen, supporting a slender style as long as the petal, crowned by an obtuse stigma. The germen afterward becomes an oval or globular capsule with five cells, filled with very small seeds.

This genus of plants is ranged in the first section of Linnæus's tenth class, intitled Decandria Monogynia, which includes those plants whose flowers have ten stamina and one style.

The SPECIES are,

1. **KALMIA** (*Latifolia*) foliis ovatis, corymbis terminalibus. Amœn. Acad. 3. p. 19. *Kalmia with oval leaves, and flowers growing in bunches terminating the branches.* Chamædaphne foliis tini, floribus bullatis umbellatis. Catesb. Carol. 2. p. 98. tab. 98. *Dwarf Laurel with a Tinus leaf, and studded flowers growing in umbels, commonly called Ivy-tree in America.*
2. **KALMIA** (*Angustifolia*) foliis lanceolatis corymbis lateralibus. Lin. Gen. Nov. 1079. *Kalmia with spear-shaped leaves, and flowers growing in round bunches on the sides of the stalk.* Chamædaphne sempervirens, foliis

K A L

oblongis angustis, foliorum fasciculis oppositis. Catesb. Carol. 3. p. 17. *Evergreen Dwarf Laurel, with oblong narrow leaves growing in bunches, which are placed opposite.* The first sort grows naturally upon rocks and in barren soils in Virginia and Pensylvania, where it rises with a branching stalk to the height of ten or twelve feet, garnished with very stiff leaves, which are two inches long and one broad, of a lucid green on their upper side, but of a pale green on their under; they have short foot-stalks, and stand without order round the branches; between these the buds are formed for the next year's flowers, at the extremity of the branches; these buds swell during the autumn and spring months, till the beginning of June, when the flowers burst out from their empalements, forming a round bunch (or corymbus) sitting very close to the branch; they are of a pale blush colour, the outside of the petal is of a Peach colour. The flower has but one petal, whose base is tubulous, but is cut into five roundish segments, studded with purple spots, which are prominent; after the flowers are past, the germen in the center becomes an oval capsule, crowned by the permanent style, having five cells, which are full of very small seeds. This shrub in its native soil continues flowering great part of the summer, and is one of the greatest ornaments to the country; but as yet it is not so well naturalized to our climate as could be wished, though the plants are not injured by the cold, and some of them have flowered several years past in the Chelsea garden.

K A R

In the country where this shrub grows naturally, it sends out plenty of suckers from the roots, so that they form thickets which are almost impassable; but here they have not as yet produced any suckers, nor do the seeds come to maturity, so that the plants are not very common in England; for the seeds which are sent from America lie in the ground a whole year before the plants appear, and afterward they make very slow progress, which has discouraged most people from attempting to raise the plants in that method. The only person who has succeeded well in the raising of these, is Mr. James Gordon of Mile End, who has a good number of the plants which have arisen from seeds.

The second sort is a native of the same country with the first, where it rises from three to six feet high, dividing into small ligneous branches which are very close, covered with a dark gray bark, garnished with stiff leaves about two inches long and half an inch broad, of a lucid green, placed without order upon the branches, standing upon slender foot-stalks; the flowers grow in loose bunches on the side of the branches, upon slender foot-stalks; they are of one petal, having a short tube, but spread open at the top, where they are cut into five angles: the flowers are of a bright red colour when they first open, but afterward fade to a blush or Peach bloom colour; these are succeeded by roundish compressed seed-vessels crowned by the permanent style, divided into five cells, which are filled with small roundish seeds. This shrub flowers great part of summer in its native country, but is not yet so well naturalized to this country as to do the like.

The leaves of this elegant plant are supposed to have a noxious quality, destroying sheep and oxen when they feed upon them, yet the deer eat them with impunity.

Both these sorts multiply by their creeping roots in their native soil, and at Whitton, where they have stood unremoved a considerable time, they put out suckers in pretty great plenty; and as these plants which come from suckers, are much more likely to produce others than those which are raised from seeds, and will flower much sooner, so the plants should not be removed, but encouraged to spread their roots and send out suckers.

KARATAS, the Penguin or wild Ananas.

The CHARACTERS are,

It hath a tubulous bell-shaped flower, which is divided into three parts at the mouth, from whose empalement where the germen is situated arises the pointal, fixed like a nail in the hinder part of the flower, attended by six short stamina; the germen afterward becomes a fleshy almost conical fruit, which is divided by membranes into three cells, that are full of oblong seeds.

There is but one sort of this plant at present known in England, which is,

KARATAS (*Penguin*) foliis ciliato spinosis mucronatis, racemo terminali. *The wild Ananas or Penguin.*

Father Plumier has made a great mistake in the figure and description of the characters of this plant, and the Caraguata; for he has joined the flower of the Caraguata to the fruit of the Karatas, and vice versa; this has led many persons into mistakes, who have joined the Bromelia and Ananas to this, making them all of the same genus, whereas by their characters they should be separated.

This plant is very common in the West-Indies, where the juice of its fruit is often put into punch, being of a sharp acid flavour. There is also a wine made of the juice of this fruit which is very strong, but it will not keep good very long, so is only for present use. This wine is very intoxicating and heats the blood, therefore should be drank very sparingly.

In England this plant is preserved as a curiosity, for the fruit seldom arrives to any degree of perfection in this country, though it has often produced fruit in the gardens, which sometimes has ripened pretty well, but if it were to ripen as thoroughly here as in its native country, it would be little valued on account

K Æ M

of its great austerity, which will often take the skin off from the mouths and throats of those people who eat it incautiously.

This plant is propagated by seeds, for though there are often suckers sent forth from the old plants, yet they come out from between the leaves, and are so long, slender, and ill-shapen, that if they are planted they seldom make regular plants. These seeds should be sown early in the spring, in small pots filled with light rich earth, and plunged into a hot-bed of tanners bark. When the plants are strong enough to transplant, they should be carefully taken up, and each planted into a separate pot filled with light rich earth, and plunged into the hot-bed again, observing to refresh them frequently with water, until they have taken new root, after which time they should have air and water in proportion to the warmth of the season. In this bed the plants may remain till Michaelmas, at which time they should be removed into the stove, and plunged into the bark-bed, where they should be treated in the same manner as the Ananas.

These plants will not produce their fruit in England until they are three or four years old, so they should be shifted into larger pots, as the plants advance in their growth; for if their roots are too much confined, they will make but little progress. They should also be placed at a pretty great distance from each other, for their leaves will be three or four feet long, which turning downward occupy a large space.

The leaves of this plant are strongly armed with crooked spines, which renders it very troublesome to shift or handle the plants; for the spines catch hold of whatever approaches them by their crooked form, being some bent one way, and others the reverse, so that they catch both ways, and tear the skin or clothes of the persons who handle them, where there is not the greatest care taken of them.

The fruit of this plant is produced in clusters, growing upon a stalk about three feet high, and having generally a tuft of leaves growing on the top, so has, at first sight, the appearance of a Pine Apple; but, when closer viewed, they will be found to be a cluster of oblong fruit, each being about the size of a finger.

A KATKIN is an aggregate of summits, hanging down in form of a rope, or Cat's tail, as in the Sallow, Hazel, Birch, &c. and is called in Latin *ulus*.

KÆMPFERIA. Lin. Gen. Plant. 7.

The CHARACTERS are,

It hath a single spathe (or sheath) of one leaf; the flower hath one petal, with a long slender tube, divided into six parts above; three of them are alternately spear-shaped and equal, the other are oval, and at bottom cut into two segments which are vertically heart-shaped. It hath but one stamina, which is membranaceous, oval, and indented, terminated by a linear summit, fastened to it all the length, scarcely emerging out of the tube of the petal. It hath a round germen supporting a style the length of the tube, crowned by an obtuse stigma; the germen afterward becomes a roundish three-cornered capsule with three cells, filled with seeds.

This genus of plants is ranged in the first section of Linnæus's first class, intitled Monandria Monogynia, which includes those plants whose flowers have one stamen and one style.

The SPECIES are,

1. **KÆMPFERIA** (*Galanga*) foliis ovatis sessilibus. Flor. Zeyl. 8. *Kempferia with oval leaves sitting close to the root.* Katsjuli Kelengu. Hort. Mal. and the Wanhom. Kæmpf. Amœn. 901. *Galangale.*
2. **KÆMPFERIA** (*Rotunda*) foliis lanceolatis petiolatis. Flor. Zeyl. 9. *Kempferia with spear-shaped leaves having foot-stalks.* Zedoaria rotunda. C. B. P. Round Zedoary. These plants are both natives of the East-Indies, where their roots are greatly used in medicine as sudorific and carminative. The first sort hath much the scent of green Ginger, when fresh taken out of the ground; the roots are divided into several fleshy tubers, which are sometimes jointed, and grow about four or five inches long; the leaves are oval, about four inches long

K I G

and two broad; these are without foot-stalks, growing close to the root, and seem as if set on by pairs, spreading open each way; and from between these leaves the flowers are produced singly, having no foot-stalks, but are closely embraced by the leaves; the flowers are white, having a bright purple bottom. These are not succeeded by any fruit in England.

The second sort hath roots somewhat like those of the first, but are shorter, growing in large clusters, covered with an Ash-coloured skin, but within are white; from the roots arise the leaves, which fold over each other at their base; they are six or eight inches long, and three broad in the middle, gradually ending in acute points; the flowers arise immediately from the roots, each having a spatha (or sheath) at bottom cut into two segments, which closely embrace the foot-stalk; these have six petals, the three lower which decline downward are long and narrow, the two upper are divided so deeply as to appear like a flower with four petals, and the side petal is bilid; they are of mixed colours, blue, purple, white and red, having a fragrant odour: they flower in July and August, but do not produce seeds in England.

These plants being natives of hot countries, will not bear the open air in England, so requires a warm stove to preserve them through the winter; but as their leaves decay in the autumn, so the plants should not have too much wet while they are in an inactive state. If the plants are placed in the bark-stove, and treated in the same manner as is directed for the Ginger, they will thrive, and produce plenty of flowers every summer. They are both propagated by parting of their roots; the best time for this is in the spring, just before they begin to put out their leaves.

KETMIA. See HIBISCUS.

KIGGELARIA. Lin. Gen. Plant. 1001. Laurus. Sterb. We have no English title for this plant.

The CHARACTERS are,

It hath male and hermaphrodite flowers situated on different trees; the male flowers have an empalement of one leaf, cut into five concave segments, and five concave petals which are longer than the empalement, shaped like a pitcher; each of the petals have a honey gland fastened to their base, which have three obtuse lobes and are coloured, fastened to the tails of the petals; they have ten small stamina, terminated by oblong summits. The hermaphrodite flowers have empalements and petals like the male, but few of them have stamina. In the center is situated a roundish germen, supporting five styles, crowned by obtuse stigmas. The germen afterward becomes a rough globular fruit with a thick cover, having one cell, filled with angular seeds.

This genus of plants is ranged in the ninth section of Linnaeus's twenty-second class, intitled Dioecia Decandria; but it should be removed to his twenty-third class, as the hermaphrodite flowers are fruitful, tho' they are situated upon distinct plants, whose male flowers have ten stamina.

We have but one SPECIES of this genus, viz.

KIGGELARIA (Africana.) Hort. Cliff. 462. fol. 29. Euonymo-affinis Æthiopica sempervirens, fructu globoso scabro, foliis salicis rigidis serratis. H. L. 139. *An Ethiopian Evergreen plant resembling the Spindle-tree, with a rough globular fruit, and stiff sawed Willow leaves.*

This plant grows naturally at the Cape of Good Hope, where it rises to be a tree of middling stature; but as it will not live in the open air here, they cannot be expected to grow to a great magnitude in England. There are plants of it in the Chelsea garden upward of ten feet high, with strong woody stems and pretty large heads; the branches have a smooth bark, which is first green, but afterward changes to a purplish colour; the leaves are about three inches long and one broad, of a light green colour, and sawed on their edges, standing upon short foot-stalks alternately. The flowers come out in clusters from the side of the branches, and hang downward; they are of an herba-

K I T

ceous white colour, and appear in May, at which time the plants are thinly garnished with leaves, for most of the old leaves drop just before the new ones appear. The male flowers fall away soon after their farina is shed, but the hermaphrodite flowers are succeeded by globular fruit about the size of common red Cherries; the cover of these is very rough, and of a thick consistence, opening in five valves at the top, having one cell filled with small angular seeds. These fruit have grown to their full size in the Chelsea garden, but the seeds have rarely come to maturity here.

These plants were not very common in Europe some years past, being very difficult to propagate, unless by seeds, which some plants both in Holland and England have lately produced, so that they are now much more plenty than they were in both countries; for when any of the young branches are laid down, they are two years before they put out roots, and scarce one in five will then have any roots; nor do the cuttings succeed better, for not one in twenty of them will take root, when planted with the utmost care: the best time to plant the cuttings is in the spring, just before the plants begin to shoot; these should be planted in pots filled with a soft loamy earth, and plunged into a very moderate hot-bed, covering them close with a glass, to exclude the air from them, and shade them every day from the sun; they should have very little water after their first planting. If any of them grow, they should be planted into separate small pots, filled with loamy earth, and may be exposed to the air in a sheltered situation till autumn, when they must be removed into the green-house, and treated in the same manner as Orange-trees.

KITCHEN-GARDEN. A good Kitchen-garden is almost as necessary to a country seat, as a kitchen to the house; for without one, there is no way of being supplied with a great part of necessary food; the markets in the country being but poorly furnished with esculent herbs, and those only upon the market days, which are seldom oftener than once a week; so that unless a person has a garden of his own, there will be no such thing as procuring them fresh, in which their goodness consists; nor can any variety of these be had in the country markets; therefore whoever proposes to reside in the country, should be careful to make choice of a proper spot of ground for this purpose; and the sooner that is made and planted, the produce of it will be earlier in perfection; for fruit-trees and Asparagus require three years to grow, before any produce can be expected from them; so that the later the garden is made, the longer it will be before a supply of these things can be had for the table. And although the usefulness of this garden is acknowledged by almost every one, yet there are few who make a proper choice of soil and situation for such a garden; the modern taste, which is, perhaps, carried to as extravagant lengths, in laying open and throwing every obstruction down, as the former custom of inclosing within walls was ridiculous; so that now one frequently sees the Kitchen-garden removed to a very great distance from the house and offices, which is attended with great inconveniencies; and often situated on a very bad soil, sometimes too moist, and at others without water, so that there is a great expence in building walls and making the garden, where there can be little hopes of success.

Nor will a Kitchen-garden be well attended to, when it is so situated as to be out of sight of the possessor, especially if the gardener has not a love and value for it, or if it lies at a great distance from his habitation, or the other parts of the garden; for when it so happens, a great part of the labourer's time will be lost in going from one part to the other: therefore, before the general plan of the pleasure-garden is settled, a proper piece of ground should be chosen for this purpose, and the plan so adapted, as that the Kitchen-garden may not become offensive to the sight, which may be effected by proper plantations of shrubs to screen the walls; and through these shrubs may be contrived

K I T

contrived some winding walks to lead to the Kitchen-garden, which will have as good an effect as those which are now commonly made in gardens for pleasure only. In the choice of the situation, if it does not obstruct the view of better objects, or shut out any material prospect, there can be no objection to the placing it at a reasonable distance from the house or offices; for as particular things may be wanted for the kitchen, which were not thought of at the time when directions were given to the gardener what to bring in; so if the garden is situated at a great distance from the house, it will be found very inconvenient to send thither as often as things are wanting: therefore it should be contrived as near the stables as possible, for the convenience of carrying the dung thither; which, if at a great distance, will add to the expence of the garden.

As to the figure of the ground, that is of no great moment, since in the distribution of the quarters all irregularities may be hid; though if you are at full liberty, an exact square or an oblong, is preferable to any other figure.

The great thing to be considered is, to make choice of a good soil, not too wet, nor over dry, but of a middling quality; nor should it be too strong or stubborn, but of a pliable nature, and easy to work; and if the place where you intend to make the Kitchen-garden should not be level, but high in one part and low in another, I would by no means advise the levelling it; for by this situation you will have an advantage which could not be obtained on a perfect level, which is, the having one part dry ground for early crops, and the low part for late crops, whereby the kitchen may be the better supplied throughout the season with the various sorts of herbs, roots, &c. And in very dry seasons, when in the upper part of the garden the crop will greatly suffer with drought, then the lower part will succeed, and so vice versâ; but I would by no means direct the chusing a very low moist spot of ground for this purpose; for although in such soils garden-herbs are commonly more vigorous and large in the summer season, yet they are seldom so well tasted or wholesome as those which grow upon a moderate soil; and especially since in this garden your choice fruits should be planted, it would be wrong to have a very wet soil.

This garden should be fully exposed to the sun, and by no means overshadowed with trees, buildings, &c. which are very injurious to your kitchen plants and fruit-trees; but if it be defended from the north wind by a distant plantation, it will greatly preserve your early crops in the spring; as also from the strong south-west winds, which are very hurtful in autumn to fruit and garden-herbs. But these plantations should not be too near nor very large; for I have generally found where Kitchen-gardens are placed near woods or large plantations, they have been much more troubled with blights in the spring, than those which have been more exposed.

The quantity of ground necessary for a Kitchen-garden must be proportioned to the largeness of the family, or the quantity of herbs desired: for a small family, one acre of ground may be sufficient; but for a large family, there should not be less than three or four acres; because, when the ground is regularly laid out, and planted with espaliers of fruit-trees, as will hereafter be directed, this quantity will be found little enough, notwithstanding what some persons have said on this head.

This ground must be walled round, and if it can be conveniently contrived, so as to plant both sides of the walls which have good aspects, it will be a great addition to the quantity of wall fruit; and those slips of ground which are without side of the walls, will be very useful for planting of Gooseberries, Currants, Strawberries, and some sorts of kitchen plants, so that they may be rendered equally useful with any of the quarters within the walls; but these slips should not be too narrow, lest the hedge, pale, or plantation

K I T

of shrubs, which inclose them, should shade the borders where the fruit-trees stand: the least width of these slips should be twenty-five or thirty feet, but if they are double that, it will be yet better, and the slips will be more useful, and the fruit-trees will have a larger scope of good ground for their roots to run. These walls should be built about twelve feet high, which will be a sufficient height for any sort of fruit. If the soil where you intend to place your Kitchen-garden be very strong, then you should plough or dig it three or four times before you plant any thing therein; and if you throw it up in ridges to receive the frost in winter, it will be of great service to meliorate and loosen its parts.

The manure which is most proper for such soils, is sea-coal ashes, and the cleansing of streets or ditches, which will render it light much sooner than any other dung or manure; and the greater the quantity of ashes the better, especially if the ground be cold; and where these ashes are not to be obtained in plenty, sea-sand is a very proper dressing, where it can be easily procured, or rotten wood, or the parts of vegetables rotted are very good; all which will greatly loosen the soil, and cause it to be not only easier to work, but also more advantageous for the growth of plants.

But, on the contrary, if your soil be light and warm, you should manure it with rotten neats dung, which is much preferable to any other dressing for hot soils; but if you use horse dung, it must be well rotted, otherwise it will burn up the crops upon the first hot dry weather.

The soil of this garden should be at least two feet deep, but if deeper it will be still better, otherwise there will not be depth enough of soil for many sorts of esculent roots, as Carrots, Parsneps, Beets, &c. which run down pretty deep in the ground, and most other sorts of esculent plants delight in a deep soil; and many plants, whose roots appear short, yet if their fibres by which they receive their nourishment are traced, they will be found to extend to a considerable depth in the ground; so that when these are stopped by meeting with gravel, chalk, clay, &c. the plants will soon shew it by their colour and stunted growth.

You should also endeavour to have a supply of water in the different parts of the garden, which, if possible, should be contained in large basins or reservoirs, where it may be exposed to the open air and sun, that it may be softened thereby; for such water as is taken out of wells, &c. just as it is used, is by no means proper for any sort of plants.

In the distribution of this garden, after having built the walls, you should lay out banks or borders under them, which should be at least eight or ten feet broad, whereby the roots of the fruit-trees will have greater liberty than in such places where the borders are not above three or four feet wide; and upon these banks you may sow many sorts of early crops, if exposed to the south; and upon those exposed to the north, you may have some late crops; but I would by no means advise the planting any sort of deep rooting plants too near the fruit-trees, especially Peas and Beans; tho' for the advantage of the walls, to preserve them in winter, and to bring them forward in the spring, the gardeners in general are too apt to make use of those borders, which are near the best aspected walls, to the great prejudice of their fruit-trees; but for these purposes it is much better to have some Reed-hedges fixed in some of the warmest quarters, under which you should sow and plant early Peas, Beans, &c. where they will thrive as well as if planted under a wall, and hereby your fruit-trees will be entirely freed from such troublesome plants.

Then you should proceed to dividing the ground out into quarters, which must be proportioned to the largeness of the garden; but I would advise never to make them too small, whereby your ground will be lost in walks; and the quarters being inclosed by espaliers of fruit-trees the plants therein will draw up slender, and

K I T

and never arrive to half the size as they would do in a more open exposure.

The walks of this garden should be also proportioned to the size of the ground, which in a small garden should be four feet, but in a large one six; and on each side of the walk should be allowed a border five or six feet wide between the espalier and the walk, whereby the distance between the espaliers will be greater, and the borders being kept constantly worked and manured, will be of great advantage to the roots of the trees; and in these borders may be sown some small sallad, or any other herbs, which do not continue long or root deep, so that the ground will not be lost.

The breadth of these middle walks which I have here assigned them, may by many persons be thought too great; but my reason for this is to allow proper room between the espaliers, that they may not shade each other, or their roots interfere and rob each other of their nourishment: but where the walks are not required of this breadth, it is only enlarging of the borders on each side, and so reducing the walks to the breadth desired.

But the walks of these gardens should not be gravelled, for as there will constantly be occasion to wheel manure, water, &c. upon them, they would soon be defaced, and rendered unsightly; nor should they be laid with turf; for in green walks, when they are wheeled upon or much trodden, the turf is soon destroyed, and those places where they are much used, become very unsightly also; therefore the best walks for a Kitchen-garden are those which are laid with a binding sand; but where the soil is strong and apt to detain the wet, there should be some narrow underground drains made by the side of the walks, to carry off the wet, otherwise there will be no using of the walks in bad weather; and where the ground is very wet, and the water is detained by the stiffness of the soil, if some lime-rubbish, flints, chalk, or any such material as can be procured with the least expence, and is laid at the bottom of these walks; or if neither of these can be had, a bed of Heath or Furze should be laid, and the coat of sand laid over it; the sand will be kept drier, and the walks will be sound and good in all seasons. These sand-walks when they are well laid, are by much the easiest kept of any; for when either weeds or Moss begin to grow, it is but scuffling them over with a Dutch hoe in dry weather, and raking them over a day or two after, and they will be as clean as when first laid.

The best figure for the quarters to be disposed into, is a square or an oblong, where the ground is adapted to such a figure; otherwise they may be triangular, or of any other shape, which will be most advantageous to the ground.

When the garden is laid out in the shape intended, if the soil is strong, and subject to detain the moisture, or is naturally wet, there should always be underground drains made, to carry off the wet from every quarter of the garden, for otherwise most sorts of kitchen plants will suffer greatly by moisture in winter; and if the roots of the fruit-trees get into the wet, they will never produce good fruit, so that there cannot be too much care taken to let off all superfluous moisture from the Kitchen-garden.

These quarters should be constantly kept clear from weeds, and when any part of the ground is unoccupied, it should always be trenched up into ridges, that it may sweeten and imbibe the nitrous particles of the air, which is of great advantage to all sorts of land, and the ground will then be ready to lay down whenever it is wanted.

The ground in these quarters should not be sown or planted with the same crop two years together, but the crops should be annually changed, whereby they will prove much better than when they constantly grow upon the same spot. Indeed the kitchen-gardeners near London, where the land is dear, are often obliged to put the same crop upon the ground for two or three years together; but then they dig and manure

K N A

their land so well every year, as to render it almost new; though notwithstanding all this, it is constantly observed, that fresh land always produces the best crops.

In one of these quarters, which is situated nearest to the stables, and best defended from the cold winds; or if either of the slips without the garden wall, which is well exposed to the sun, lies convenient, and is of a proper width, that should be preferred for a place to make hot-beds for early Cucumbers, Melons, &c. The reasons for my giving the preference to one of these slips, is, first, there will be no dirt or litter carried over the walks of the Kitchen-garden in winter and spring, when the weather is generally wet, so that the walks will be rendered unsightly; secondly, the view of the hot-beds will be excluded from sight; and lastly, the convenience of carrying the dung into these slips, for by making of a gate in the hedge, or pale, wide enough for a small cart to enter, it may be done with much less trouble than that of barrowing it thro' the garden; and where there can be a slip long enough to contain a sufficient number of beds for two or three years, it will be of great use; because by the shifting of the beds annually, they will succeed much better than when they are continued for a number of years on the same spot of ground; and as it will be absolutely necessary to fence this Melon-ground round with a Reed-hedge, it may be so contrived as to move away in pannels; and then that hedge which was on the upper side the first year, being carried down to a proper distance below that which was the lower hedge, and which may remain, there will be no occasion to remove more than one of the cross hedges in a year; therefore I am persuaded, whoever will make trial of this method, will find it the most eligible.

The most important points of general culture consist in well digging and manuring the soil, and giving a proper distance to each plant, according to their different growths (which is constantly exhibited in their several articles in this book) as also in keeping them clear from weeds; for if weeds are permitted to grow until their seeds are ripe, they will shed upon the ground, and fill it so as not to be gotten out again in several years. You should also observe to keep your dunghills always clear from weeds, for it will be to little purpose to keep the garden clean, if this is not observed; for the seeds falling among the dung, will be brought into the garden, whereby there will be a constant supply of weeds yearly introduced, to the no small damage of your plants, and a perpetual labour occasioned to extirpate them again. Another thing which is absolutely necessary to be observed, is, to carry off all the refuse leaves of Cabbages, the stalks of Beans and haulm of Pease, as soon as they are done with, for the ill scent which most people complain of in the Kitchen-gardens, is wholly occasioned by these things being suffered to rot upon the ground; therefore when the Cabbages are cut, all leaves should be carried out of the garden while they are fresh, at which time they may be very useful for feeding of hogs, or other animals, and this will always keep the garden neat and free from ill scents. As for all other necessary directions, they will be found in the articles of the several sorts of kitchen plants, which renders it needless to be repeated in this place.

KLEINI A. See CACALIA.

KNAUTIA. Lin. Gen. Plant. 109. Lychni-Scabiosa. Boerh. Ind. 1. 131.

This name was applied to this plant by Dr. Linnæus, in honour of the memory of Dr. Christian Knaut, who published a method of classing plants.

The CHARACTERS are,

It hath a single oblong empalement, containing several stellular flowers, which are ranged so as to appear regular, but each irregular, having tubes the length of the empalement, but are cut at the brim into four irregular segments, the outer being the biggest; it hath four stamina the length of the tube, inserted in the receptacle, terminated by oblong incumbent summits; and a germen under the petal, supporting a slender style, crowned by a thick bifid stigma, which

K N A

which afterward becomes a four-cornered seed with a hairy apex.

This genus of plants is ranged in the first section of Linnaeus's fourth class, intitled Tetrandria Monogynia, the flowers having four stamina and one style.

The SPECIES are,

1. KNAUTIA (*Orientalis*) foliis omnibus pinnatifidis, corollis calyce longioribus. Lin. Sp. App. 1679. *Knautia with all the leaves wing-pointed, and the petal longer than the empalement.* Lychni-scabiosa, flore rubro, annua. Boerh. Ind. alt.
2. KNAUTIA (*Propontica*) foliis superioribus lanceolatis indivisis, corollis calyce æqualibus. Lin. Sp. App. 1666. *Knautia whose upper leaves are spear-shaped and whole, and the petal of the flower equal to the empalement.* Scabiosa Orientalis villosa, flore suaverubente, fructu pulchro oblongo. Tourn. Cor. 35.

These plants are natives of the East, they are both annual; the first has been long cultivated in the English gardens; this rises with an erect branching stalk four feet high, garnished with wing-pointed leaves; the branches are terminated by single foot-stalks, each supporting one flower, having a tubular empalement cut

K N I

into four segments at the top, and each contain four florets of a bright red colour, cut into four unequal segments, the outer being much larger than the other; these have four stamina the length of the tube of the petal, terminated by oblong summits; and the flowers are succeeded by oblong four-cornered seeds, which, when ripe, soon fall out of the cup if they are not gathered.

The second sort differs from the first in its upper leaves being whole, and the petal of the flower being equal to the cup. The lower leaves of this are sawed on their edges, and terminate in acute points.

These plants propagate easily; if their seeds are permitted to scatter in the autumn, the plants will come up soon after; and if some of these are planted in the borders of the pleasure-garden, or among low shrubs near the walks in October, the plants will live through the winter, and flower in June; so their seeds will ripen the end of July or beginning of August, therefore require no other culture but to keep them clean from weeds.

KNIGHTS CROSS, or SCARLET CROSS, is the Scarlet Lychnis. See LYCHNIS.

L.

L A B

LABIATE FLOWERS are such as have lips, or more properly a labiated flower, is an irregular monopetalous flower, divided into two lips; the upper is called the crest, the under the beard; sometimes the crest is wanting, and then the style and chives supply its place, as in the Ground Pine, Scordium, Bugula, &c. but the greatest part have two lips, which, in some species the upper lip is turned upwards, as the Ground Ivy, &c. but most usually the upper lip is convex above, and turns the hollow part down to the lower lip, and so represents a kind of helmet, or monk's hood, from whence these are called galeate, cucullate, and galericulate flowers, in which form are most of the verticillate plants.

LABLAB. See PHASEOLUS.

LABRUM VENERIS. See DIPSACUS.

LABRUSCA. See VITIS.

LABURNUM. See CYTISUS.

LABYRINTH [*Λαβύρινθος*,] a winding, mazy, and intricate turning to and fro, through a wilderness or a wood.

The design of a Labyrinth is, to cause an intricate and difficult labour to find out the center, and the aim is, to make the walks so intricate, that a person may lose himself in them, and meet with as great a number of stops and disappointments as is possible, they being the most valuable that are most intricate.

As to the contrivance of them, it will not be possible to give directions in words, there are several plans and designs in books of gardening; they are rarely met with but in great and noble gardens, as Hampton-court, &c.

There are two ways of making them, the first is with single hedges; this method has been practised in England. These, indeed, may be best, where there is but a small spot of ground to be allowed for the making

L A C

them, but where there is ground enough, the double are most eligible.

Double ones, or those that are made with double hedges of a considerable thickness of wood between hedge and hedge, are approved as much better than single ones, as is the manner of making them in France, and other places, of all which, that of Versailles is allowed by all to be the noblest of its kind in the world.

It is an error in Labyrinths in making them too narrow, for by that means the hedges must be kept close clipped; whereas, if the walks are made wider, according to the foreign practice, they will not stand in so much need of it.

The walks are made with gravel, and the hedges are usually set with Hornbeams; the pallisades ought to be ten, twelve, or fourteen feet high; the Hornbeam should be kept cut, and the walks rolled.

LACRYMA JOBI [so called, because the seed of it resembles a tear, or drop.] Job's Tears. See COIX.

LACTIFEROUS PLANTS are such as abound with a milky juice, as the Euphorbia, Sonchus, Lactuca, &c.

LACTUCA. Tourn. Inst. R. H. 473. tab. 267. Lin. Gen. Plant. 814. [so called from lac, Lat. milk, because the leaves, stalks, flower, and branch, being broken, plentifully emit a milk, or white milky juice, quickly turning yellow and bitterish.] Lettuce; in French, *Laitue*.

The CHARACTERS are,

The flowers are composed of several hermaphrodite florets, inclosed in one scaly oblong empalement; these lie over each other like the scales of fish. The florets have one petal, which is stretched out on one side like a tongue, and is slightly indented at the end in three or four parts; these have each five short hairy stamina; the oval germen supports

ports a slender style, crowned by two reflexed stigmas, and afterward becomes one oblong pointed seed, crowned with a single down, sitting in the scaly empalement.

This genus of plants is ranged in the first section of Linnaeus's nineteenth class, intitled Syngenesia Polygamia æqualis, which includes those plants whose flowers are composed of all hermaphrodite, or fruitful florets, and have their stamina and style connected.

It would be beside my purpose to mention in this place the several sorts of Lettuce that are to be found in botanic writers, many of which are plants of little use, and are never cultivated but in botanic gardens for variety; some of them are found wild in many parts of England. I shall therefore pass over those, and only mention the several varieties which are cultivated in the kitchen-garden for use: 1. Common or Garden Lettuce. 2. Cabbage Lettuce. 3. Cilicia Lettuce. 4. Dutch Brown Lettuce. 5. Aleppo Lettuce. 6. Imperial Lettuce. 7. Green Capuchin Lettuce. 8. Versailles, or Upright White Cos Lettuce. 9. Black Cos. 10. Red Capuchin Lettuce. 11. Roman Lettuce. 12. Prince Lettuce. 13. Royal Lettuce. 14. Egyptian Cos Lettuce.

The first of these sorts is commonly sown for cutting very young, to mix with other small salad herbs, and is only different from the second sort, in being a degeneracy therefrom, or otherwise the second is an improvement by frequent cultivation from the first; for if the seeds are saved from such plants of the second sort as did not cabbage closely, the plants produced from that seed will degenerate to the first sort, which is by the gardeners called Lapped Lettuce, to distinguish it from the other, which they call Cabbage Lettuce. The seeds of the first, which are commonly saved from any of the plants, without having regard to their goodness, are generally sold at a very cheap rate (especially in dry seasons, when these plants always produce the greatest quantity of seeds,) though sometimes this seed is sold in the seed-shops, and by persons who make a trade of selling seeds, for the Cabbage Lettuce, which is often the occasion of peoples being disappointed in their crop; so that this sort should never be cultivated but to be cut up very young, for which purpose this is the only good sort, and may be sown any time of the year, observing only in hot weather to sow it in shady borders; and in the spring and autumn upon warm borders, but in winter it should be sown under glasses, otherwise it is subject to be destroyed by severe frosts.

The Cabbage Lettuce may also be sown at different times of the year, in order to have a continuation of it through the whole season. The first crop is generally sown in February, which should be upon a warm spot of ground, and when the plants are come up, they should be thinned out to the distance of ten inches each way, which may be done by hoeing them out, as is practised for Turneps, Carrots, Onions, &c. provided you have no occasion for the superfluous plants, otherwise they may be drawn up, and transplanted into another spot of good ground at the same distance, which, if done before the plants are too large, they will succeed very well, though they will not be so large as those which are left upon the spot where they were sown, but they will come somewhat later, which will be of service where people do not continue sowing every fortnight or three weeks in summer.

You must also observe in sowing the succeeding crops, as the season advances, to chuse a shady moist situation, but not under the drip of trees, otherwise, in the heat of summer they will run up to seed before they cabbage. In the beginning of August you should sow the last crop, which is to stand over winter; the seeds should be sown thin upon a good light soil, in a warm situation, and when the plants are come up they must be hoed out, so as they may stand singly, and cut down all the weeds to clear them. In the beginning of October they should be transplanted into warm borders, where, if the winter is not very severe, they will stand very well; but in order to be sure of

a crop, it will be advisable to plant a few upon a bed pretty close together, where they may be arched over with hoops, and in severe frosts they should be covered with mats and straw, or Peas-haulm, to secure them from being destroyed; and in the spring of the year they may be transplanted out into a warm rich soil, at the distance before-mentioned; but still those which grew under the wall, if they escaped the winter, and were suffered to remain, will cabbage sooner than those which are removed again; but you must observe not to place them too close to the wall, which would occasion their growing up tall, and prevent their being large or hard.

In order to save good seeds of this kind, you should look over your Lettuces when they are in perfection, and such of them as are very hard, and grow low, should have sticks thrust into the ground, by the sides of as many of them as you intend for seed, to mark them from the rest; and you should carefully pull up all the rest from amongst them as soon as they begin to run up, if any happen to be left, lest when they are run up to flower, they should, by the intermixing their farina with the good ones, degenerate the seeds. It may be some persons may object, that suppose some bad ones should happen to be left among them (for seeds to sow for small salads,) yet the good ones being marked, the seeds need not be mixed, and so no danger can ensue from thence; but notwithstanding ever so much care be taken to keep the seeds separate, yet, whether from the intermixing of the farina during the time of their being in flower, or what other cause, I cannot say, but it hath been frequently observed, that where good and bad plants have been left for seed upon the same spot, the seeds of the good plants which were carefully saved separately, have very much degenerated, and proved worse than such as have seeded by themselves. The seeds should always be saved either from those which stood through the winter, or those which were sown early in the spring, for the late ones very seldom perfect their seeds.

The Cilicia, Imperial, Royal, Black, White, and Upright Cos Lettuces may be sown at the following times; the first season for sowing these seeds is at the latter end of February, or the beginning of March, upon a moderate hot-bed, or on a warm light soil in a sheltered situation; and when the plants are come up and are fit to transplant, those which were sown on the hot-bed should be planted on another warm bed about four inches asunder, row from row, and two inches distance in the rows, observing to shade them from the sun till they have taken new root; after which they should have a larger share of air admitted to them daily, to prevent their drawing up weak; but if the season proves favourable, they should be transplanted the beginning of April to the place where they are to remain, allowing them sixteen inches room every way, for these large sorts must not be planted too near each other; those which were sown in the full ground will be later before they come up, so should be either hoed out, or transplanted into another spot of ground (as was directed for those sown on the hot-bed allowing them as much room) especially if the soil be good; after they have taken new root, you must carefully keep them clear from weeds, which is the only culture they will require, except the Black Cos Lettuce, which should be tied up when they are full grown (in the manner as was directed for blanching of Endive,) to whiten their inner leaves, and render them crisp, otherwise they are seldom good for much, rarely cabbaging without this assistance.

When your Lettuces are in perfection, you should look over them, and mark as many of the best of them as you intend for seed (in the same manner as was before directed for the common Cabbage Lettuce,) being very careful not to suffer any ordinary ones to seed amongst them, as was before observed, which would prove more injurious to these sorts than to the common, as being more inclinable to degenerate with us, if they are not carefully saved.

You

L A C

You may also continue these sorts through the whole season of Lettuce, by sowing them in April, May, and June, observing, (as was before directed) to sow the late crops in a shady situation, otherwise they will run up to seed before they grow to any size; but in the middle of September you may sow of these sorts, to abide the winter; which plants should be transplanted either under glasses, or into a bed, which should be arched over with hoops, in order to be covered in the winter, otherwise in hard winters they are often destroyed; but you must constantly let these plants have as much free air as possible, when the weather is mild, only covering them in hard rains or frosty weather; for if they are kept too closely covered in winter, they will be subject to a mouldiness, which soon rots them.

In the spring these plants should be planted out into a rich light soil, allowing them at least sixteen inches distance each way; for if they are planted too close, they are very subject to grow tall, but seldom cabbage well; and from this crop, if they succeed well, it will be proper to save your seeds; though you should also save from that crop sown on the hot-bed in the spring, because sometimes it happens, that the first may fail by a wet season, when the plants are full in flower, and the second crop may succeed, by having a more favourable season afterwards; and if they should both succeed, there will be no harm in that, since the seeds will grow very well when two years old, and if well saved, at three, but this will not always happen.

The most valuable of all the sorts of Lettuce in England, are the Egyptian Green Cos, and the Versailles, or White Cos, and the Cilicia, though some people are very fond of the Royal and Imperial Lettuces, but they seldom sell so well in the London markets as the other, nor are so generally esteemed. Indeed of late years, since the White Cos has been commonly cultivated, it has obtained the preference of all the other sorts, until the Egyptian Green Cos was introduced, which is so much sweeter and tenderer than the White Cos, that it is by all good judges esteemed the best sort of Lettuce yet known. This sort will endure the cold of our ordinary winters full as well as the White Cos; but at the season of its cabbaging, if there happens to be much wet, this being very tender, is very subject to rot.

The Brown Dutch and Green Capuchin Lettuces are very hardy, and may be sown at the same seasons as was directed for the common Cabbage Lettuce, and are very proper to plant under a wall, or hedge, to stand the winter, where many times these will abide, when most of the other sorts are destroyed, and therefore they will prove very acceptable at a time when few other sorts are to be had; they will also endure more heat and drought than most other sorts of Lettuce, which renders them very proper for late sowing; for it very often happens, in very hot weather, that the other sorts of Lettuce will run up to seed in a few days after they are cabbaged, whereas these will abide near a fortnight in good order, especially if care be taken to cut the forwardest first, leaving those that are not so hard cabbaged to be last. If some plants of these two last sorts are planted under frames, on a moderate hot-bed in October, they will be fit for use in April, which will prove acceptable to those who are lovers of Lettuce, and being covered by glasses, will render them tender. In saving of these seeds, the same care should be taken to preserve only such as are very large and well cabbaged, otherwise the seeds will degenerate, and be good for little.

The Red Capuchin, Roman, and Prince Lettuces are pretty varieties, and cabbage very early, for which reason a few of them may be preserved, as may also some of the Aleppo, for the beauty of its spotted leaves; though very few people care for either of these sorts at table, when the other more valuable ones are to be obtained; but in a scarcity, these may supply the place pretty well, and these sorts are very proper for soups. The seeds of these must also be saved from

L A M

such as cabbage best, otherwise they will degenerate, and be good for little.

In saving seeds of all these sorts of Lettuce, you should observe never to let two sorts stand near each other, for by their farina mixing, they will both vary from their original, and partake of each other; and there should be a stake fixed down by the side of each, to which the stem should be fastened, to prevent their being broken, or blown out of the ground by wind, to which the Cilicia, Cos, and the other large growing Lettuces, are very subject when they are in flower. You must also observe to cut such branches of the large growing Lettuce as ripen first, and not wait to have the seed of the whole plant ripe together, which never happens; but, on the contrary, some branches will be ripe a fortnight or three weeks before others; and when you cut them, they must be spread upon a coarse cloth in a dry place, that the seeds may dry, after which you should beat them out, and dry them again, and then preserve them for use, being careful to hang them up where mice and other vermin cannot come at them; for if they do, they will soon eat them up.

LACTUCA AGNINI. See **VALERIANELLA**.

LADY'S SLIPPER. See **CYPRIPEDIUM**.

LADY'S SMOCK. See **CARDAMIN**.

LAGOECIA, Bastard Cumin.

The **CHARACTERS** are,

It hath many flowers collected into a head, which have one common empalement, composed of eight indented leaves, but the simple empalement to each flower hath five leaves, which are very narrow and pinnated, ending in many hair-like points. The flower consists of five horned petals, which are shorter than the empalement; at the bottom of each flower is situated the germen, supporting a style crowned by a simple stigma, attended by five stamina, which are long and narrow; the germen afterward changes to an oval seed, crowned with the empalement.

There is but one **SPECIES** of this plant, viz.

LAGOECIA (*Cuminoides*.) Lin. Hort. Cliff. Bastard, or Wild Cumin.

We have no other English name for this plant, nor is this a very proper one, but as it has been titled by some of the antient botanists *Cuminum sylvestre*, i. e. Wild Cumin, and by Dr. Tournefort it is made a distinct genus, by the title of *Cuminoides*, it may be styled Wild, or Bastard Cumin.

This is an annual plant, which grows about a foot high. The leaves resemble those of the Honeywort. The flowers, which are of a greenish yellow colour, are collected in spherical heads at the extremity of the stalks; but there being little beauty in the plant, it is rarely cultivated, except in botanic gardens. It grows plentifully about Aix, in Provence, as also in most of the islands of the Archipelago. It is annual, and perishes soon after the seeds are ripe. The seeds of this plant should be sown in autumn on a warm border, soon after they are ripe; or if they are permitted to scatter, the plants will come up, and require no other care but to clear them from weeds. When the seeds are sown in the spring, they commonly remain in the ground a year before they grow, and sometimes I have known them to lie two or three years in the ground, so that if the plants do not come up the first year, the ground should not be disturbed.

LAGOPUS. See **TRIFOLIUM**.

LAMINATED signifies platted. Those things are said to be laminated, whose contexture discovers such a disposition as that of plates lying over one another, or the scales of fish.

LAMIUM. Tourn. Inst. R. H. 183. tab. 89. Lin. Gen. Plant. 636. Dead Nettle, or Archangel.

The **CHARACTERS** are,

The flower hath a permanent empalement of one leaf, which is tubulous, and cut into five equal segments at the top, which end in beards. The flower is of the lip kind; it hath one petal, with a short cylindrical tube, swollen at the chaps and compressed; the upper lip is arched, roundish, obtuse, and entire; the under is short, heart-shaped, reflexed, and indented at the end. It hath four awl-shaped stamina

L A M

stamina joined to the upper lip, two of which are longer than the other, terminated by oblong hairy summits. It hath a four-cornered germen, supporting a slender style situated with the stamina, and crowned by an acute two-pointed stigma; the germen afterward become four three-cornered seeds, sitting in the open empalement.

This genus of plants is ranged in the first section of Linnæus's fourteenth class, intitled *Didynamia Gymnospermia*, in which he ranges those plants whose flowers have two long and two shorter stamina, and are succeeded by naked seeds sitting in the empalement.

The SPECIES are,

1. **LAMIUM** (*Purpureum*) foliis cordatis obtusis petiolatis. Hort. Cliff. 314. *Dead Nettle with heart-shaped obtuse leaves standing on foot-stalks. Lamium purpureum foetidum, folio subrotundo, five Galeopsis Dioscoridis. C. B. P. Purple stinking Archangel, or Dead Nettle, or the Galeopsis of Dioscorides with a roundish leaf.*
2. **LAMIUM** (*Album*) foliis cordatis acuminatis serratis petiolatis. Hort. Cliff. 314. *Dead Nettle with pointed heart-shaped leaves, which are sawed, and have foot-stalks. Lamium album, non foetens, folio oblongo. C. B. P. White Archangel or Dead Nettle which does not stink, with an oblong leaf.*
3. **LAMIUM** (*Garganicum*) folis cordatis pubescentibus, corollis fauce inflata, tubo recto dente utrinque gemino. Lin. Sp. 808. *Dead Nettle with heart-shaped hairy leaves, and the chaps of the flower inflated, indented with two teeth. Lamium garganicum subincanum, flore purpurascens, cum labio superiore crenato. Micheli. Hoary Dead Nettle with a purplish flower, whose upper lip is crenated.*
4. **LAMIUM** (*Moschatum*) foliis cordatis obtusis glabris, floralibus sessilibus, calycibus profundè incis. *Dead Nettle with heart-shaped, obtuse, smooth leaves, the upper sitting close to the stalks, and empalements deeply cut. Lamium Orientale, nunc moschatum, nunc foetidum, magno flore. Tourn. Cor. Eastern Dead Nettle, sometimes sweet-scented and sometimes stinking, with a large flower.*
5. **LAMIUM** (*Melissifolium*) foliis cordatis nervosis serratis, petiolis longioribus, caule erecto. *Dead Nettle with heart-shaped veined leaves which are sawed, and longer foot-stalks with an erect stalk. Lamium montanum melissæ folio. C. B. P. 231. Icon. Pl. 158. Mountain Dead Nettle with a Balm leaf.*

There are several other species of this genus, as also some varieties of it, but as most of them are weeds, I have passed them over, for there are few who care to admit them into their gardens.

The first sort grows naturally in most parts of England, under hedges and by the side of highways; it is also a troublesome weed in gardens, but as it stands in most of the dispensaries as a medicinal plant, I have chosen to insert it. This is an annual plant, whose stalks seldom rise more than four or five inches high; the under leaves are heart-shaped, blunt, and stand upon pretty long foot-stalks, but the upper leaves sit nearer to the stalks; the flowers come out in whorls on the upper part of the stalk; they are of a pale purple colour, and are succeeded by four naked seeds sitting in the empalement; after the seeds are ripe the plant decays. It flowers in the middle of March, when the autumnal self-sown plants appear; these are succeeded by others, which continue in succession all the summer.

The second sort is commonly called Archangel; this is also used in medicine, for which reason I have enumerated it here. The roots of this are perennial, and creep much in the ground, so is difficult to extirpate, where it happens to grow under bushes and hedges; for the roots intermix with those of the bushes, and every small piece of them grow and spread. The stalks of this rise much higher than those of the last, the flowers are larger, white, and grow in whorls round the stalks; these continue in succession most part of the summer.

The third sort grows naturally upon the mountains

L A N

in Italy; this hath a perennial creeping root, from which arise many thick square stalks a foot high, garnished with heart-shaped leaves which are hairy, placed opposite, standing upon pretty long foot-stalks; the flowers come out in whorls at the upper joints of the stalk, they are large, and of a pale purplish colour; these continue in succession most part of the summer, and the flowers are succeeded by seeds which ripen about six weeks after. This may be propagated by seeds, but as the roots spread greatly in the ground, so when once it is obtained, it will propagate fast enough without culture.

The fourth sort grows naturally in the Archipelago; this is an annual plant, which, if permitted to scatter its seeds, the plants will come up and thrive better than when sown by the hand. The plants come up in the autumn, and during the winter their leaves make a pretty appearance, for they are marked with white somewhat like those of the autumnal Cyclamen; the stalks rise eight or nine inches high, and are garnished with smooth heart-shaped leaves placed opposite; these in dry weather have a musky scent, but in wet weather are fetid; the flowers are white, standing in whorls round the stalks. They appear in April, and the seeds ripen in June, then the plants decay; this requires no culture, but to keep the plants clear from weeds.

The fifth sort grows naturally in Portugal; this hath a perennial root and an annual stalk, which rises a foot and a half high; it is strong, square, and grows erect; the leaves are large, heart-shaped, and much veined; they are deeply sawed on their edges, and are placed opposite. The flowers come out in whorls round the stalks at every joint; they are very large, and of a deep purple colour; those on the lower part of the stalks appear the beginning of May, which are succeeded by others above, so that there is a continuance of flowers almost two months on the same stalks. This plant very rarely produces good seeds in England, nor do the roots propagate very fast, so that it is not common here.

The best time to remove and part these roots is in October, but they must not be transplanted oftener than every third year if they are required to flower strongly; for the great beauty of this plant consists in the number of stalks, which are always proportional to the size of the plants; for small plants will put out one or two stalks only, whereas the larger ones will have eight or ten. The roots are hardy, and will thrive best in a soft loamy soil.

LAMPSANA. See **LAPSANA.**

LAND. Its improvement.

1. By inclosing.

Inclosing of Lands, and dividing the same into several fields, for pasture or tillage, is one of the principal ways of improvement; first, by ascertaining to every man his just property, and thereby preventing an infinity of trespasses and injuries, that Lands in common are subject unto, beside the disadvantage of being obliged to keep the same seasons with the other people who have Land in the same field; so that the sowing, fallowing, and tilling the ground, must be equally performed by all the landholders; and when there happens a slothful negligent person, who has Land intermixed with others, it is one of the greatest nuisances imaginable. Secondly, it being of itself a very great improvement; for where Land is properly inclosed, especially in open countries, and the hedge-rows planted with timber trees, &c. it preserves the Land warm, and defends and shelters it from the violent cold nipping winds, which, in severe winters, destroy much of the corn, pulse, or whatever grows on the open field or champaign grounds. And where it is laid down for pasture, it yields much more Grass than the open fields, and the Grass will begin to grow much sooner in the spring. The hedges and trees will afford shelter for the cattle from the cold winds in winter, as also shade for them in the great heats of summer. And these hedges afford the diligent husbandman plenty of fuel, as plough-boot,

cart-boot, &c. And where they are carefully planted and preserved, furnish him with timber and also mast for his swine; or where the hedge-rows are planted with fruit-trees, there will be a supply of fruit for cyder, perry, &c. which in most parts of England are of no small advantage to the husbandman.

By this method of inclosing, there is also much more employment for the poor, and is therefore a good remedy against beggary; for in those open countries, where there are great downs, commons, heaths, and wastes, there is nothing but poverty and idleness to be seen amongst the generality of their inhabitants. It is very observable of late years, how much advantage the inclosing of the Land in Worcestershire, and some other counties at a distance from London, has been to the inhabitants: for before this method was introduced amongst them, the Lands for the most part lay in commons, &c. Upon which the poorer sort of people built themselves cottages with mud walls, where they contented themselves with a cow or two, and some swine; and those of them who were more industrious than the rest, travelled to the neighbourhood of London every spring, where they were employed in the gardens and fields for the summer season; and in autumn they returned to their native countries, where they lived in winter upon what money they had saved in summer. But since they have converted their wastes and commons into inclosures, there are but few of the inhabitants of those countries, who come to London for work, in comparison to the numbers that formerly came; so that most of the labourers, who come to London for employment, are either Welch, or inhabitants of some more distant counties, or from Ireland, where this improvement hath not as yet been introduced.

The advantages of inclosing Land are now so generally known, that there is no occasion for me to enumerate them here; since the improvements which have been made of late years in several parts of England, and the increase of rent that is every where made by those who inclose, are sufficient arguments to enforce the practice, and render it general; more especially in the north, where it is most neglected, because it would greatly shelter the Lands, and render them much warmer than they now are.

In inclosing of Land, regard should be had to the nature of the soil, and what it is intended for, because Corn Land should not be divided into small parcels; for besides the loss of ground in hedges, &c. the Corn doth seldom thrive so well in small inclosures, as in more open fields, especially where the trees are large in the hedge-rows. The Grass also in pastures is not so sweet near hedges, or under the drip of trees, as in an open exposure; so that where the inclosures are made too small, or the Land overplanted with trees, the herbage will not be near so good, nor in so great plenty, as in larger fields; therefore, before a person begins to inclose, he should well consider how he may do it to the greatest advantage; as for instance, it is always necessary to have some smaller inclosures near the habitation, for the shelter of cattle, and the convenience of shifting them from one field to another, as the season of the year may require; and hereby the habitation, barns, stables, and outhouses, will be better defended from strong winds, which often do great damage to those that are exposed to their fury. These small inclosures may be of several dimensions, some of them three, four, six, or eight acres in extent; but the larger divisions for Corn should not contain less than twenty or thirty acres or more, according to the size of the farm, or the situation of it.

The usual method of inclosing Land is, with a ditch and bank set with quick. But in marsh Land, where there is plenty of water, they content themselves with only a ditch, by the sides of which they usually plant Sallows or Poplars, which being of quick growth, in a few years afford shade to the cattle; and when they are lopped, produce a considerable profit to their owners. In some counties the division of their Lands is

by dry walls made of flat stones, laid regularly one upon another, and laying the top course of stones in clay, to keep them together, the weight of which secures the under ones. But in some parts of Sussex and Hampshire, they often lay the foundation of their banks with flat stones, which is of a considerable breadth at bottom; upon which they raise the bank of earth, and plant the hedge on the top, which in a few years makes a strong durable fence, especially if they are planted with Holly, as some of those in Sussex are.

In marshes and open pastures, where there are no hedges, the ditches are generally made six feet wide at the top, especially those which are on the side of highways or commons; but the common ditches about inclosures are seldom more than three feet and a half wide at top, and one foot and a half at bottom, and two feet deep, that the sides may have a good slope, and not be too upright, as they are frequently made about London, so that they are continually washing down with great rains. In these narrow bottomed ditches, the cattle cannot stand to turn themselves, so as to crop the quick; but where the ditches are made wider, they should be proportionally deeper: as for instance, if the ditch is made five feet broad, it must be three feet deep; and if six feet broad, three feet and a half deep, and so in proportion.

The method of inclosing Lands, by raising high banks of earth, on the side of which the quick is planted (as is too much practised in many places near London) is intolerable, for it is not only unsightly, but very expensive; because these banks are continually washing down, so that they must be repaired every year at least, if not oftener, otherwise the earth will be in a few years washed from the roots of the quick, and for want of proper nourishment, the hedge will soon decay, which is the case with the greatest number of the hedges about London: besides, it is a very uncertain way of planting quick on the side of a steep bank, where all the moisture runs off; so that if the spring should prove dry after it is planted, there is a great hazard whether half the plants will grow, and those that take seldom make much progress; whereas those planted on the plain surface, where they enjoy the advantages of sun and moisture, will in four years make a better fence than one of these bank hedges will in eight or ten, and will continue good much longer than the other. Therefore I advise, that the banks on which the hedges are to be planted, should not be raised more than one foot above the surface of the ground, where the Land is dry, and in wet Land not more than two feet, which will be enough.

I shall now mention the most proper plants for making of fences for the different soils and situations, so as to answer the expectation of the planter: and first, the white Thorn is esteemed the best for fencing, and will grow upon almost any soil and in any situation, but it succeeds best on a hazle loam. Of this there are three or four varieties, which differ in the breadth of their leaves and the size of their Haws, but that sort with the smallest leaves and Haws will make the closest fence. For it is very certain, that the branches of all sorts of trees are produced at a distance, in proportion to the size of their leaves; so that Yews, and other Evergreen trees with small leaves, will always make a closer hedge than other trees whose leaves are larger. Therefore, for the closest hedge, the smallest Haws should be chosen; but where the most vigorous shooters are required, for the advantage of lopping, there the largest Haws should be preferred. But as these hedges are usually planted from a nursery, where the Haws are promiscuously sown, it is very common to see two or three sorts planted in the same hedge; which may be easily distinguished, when they have obtained strength, by the difference of their growth. Indeed, where a person is curious in raising of his own quick, it is worth while to gather the Haws separately, and sow them apart; and each sort should be planted in a separate hedge, which will render the

hedges more equal in their growth. If these Haws are sown in the places where they are designed to remain for a fence, they will make a much greater progress in a few years, than those which are transplanted; but as the seeds remain a whole year in the ground before the plants appear, few people care to practise this method; however, those who are desirous to raise their hedges this way, should bury the Haws, by putting them in pots soon after they are ripe, and burying the pots two feet deep in the ground, where they may remain one year, then take them up and sow them; by this preparation the plants will come up the following spring; but before they are sown, the Haws should be bruised with hands, and their outer coverings washed off, whereby the seeds may be sown at a more regular distance; for as most of the Haws inclose four or five seeds, so if they are sown entire there will be as many plants arise in a cluster, which if permitted to stand, will prevent each other's growth; and in drawing out the superfluous plants, there will be great danger of injuring those which are to remain.

The next to the white Thorn is the black Thorn, which, though not so generally esteemed as the white, yet it will make an excellent fence, where proper care is taken in the planting and after management of it; and the loppings of this hedge make much the best bushes for draining of Land, and are of longer duration for dead hedges than those of any other sort of tree, and are very proper to mend gaps in fences; for their branches being beset with sharp thorns, the cattle are not so apt to crop them as the white Thorn, and some other sorts. These hedges are also better, if the stones of the Plumbs are sown on the spot where they are to remain, than where the plants are taken from a nursery; if these are sown in the autumn soon after the fruit is ripe, the plants will come up the spring following.

The Crab will also make a strong durable fence; this may be raised by sowing the kernels in the place where the hedge is designed; but then there should be great care taken of the plants while they are young, to keep them clear from weeds, as also to guard them from cattle. When these stocks have obtained strength, some of them may be grafted with Apples for cyder, where the fence is not exposed to a public road; but these grafts should not be nearer than thirty-five or forty feet, lest they spoil the hedge, by their heads overgrowing and dripping on it.

The Holly is also an excellent plant for evergreen hedges, and would claim the preference to either of the former, were it not for the slowness of its growth while young, and the difficulty of transplanting the plants when grown to a moderate size. This will grow best in cold stony Lands, where, if once it takes well, the hedges may be rendered so close and thick, as to keep out all sorts of animals, and will grow to a considerable height, and is of long duration. These hedges may be raised, by sowing the berries, either in the place where they are designed to remain, or by planting young plants of three or four years growth; but as the berries continue in the ground an entire year before the plants appear, few persons care to wait so long; therefore the usual method is, to plant the hedges with plants of the before-mentioned age. But where this is practised, they should be transplanted, either early in the autumn, or deferred till toward the end of March; then the surface of the ground should be covered with mulch near their roots after they are planted, to keep the earth moist; and if the season should prove dry, the plants should be watered at least once a week, until they have taken root, otherwise they will be in danger of miscarrying; for which reason the autumnal planting is generally preferred to the spring, especially in dry grounds.

The Alder will also make a good hedge, when planted on a moist soil, or on the side of rivers, or large ditches; and will preserve the bank from being washed away, where there are running streams; for they spread pretty much at bottom, and send forth suckers from

their roots in great plenty; but these hedges should be sheared at least once a year, in order to make them thick. These Alder hedges are very ornamental, when they are well kept in large gardens; and as they will thrive best on wet swampy Lands, where many other plants will not live, they should be selected for such situations.

Of late years the Furz has been much propagated for hedges in several parts of England, and indeed will make a good fence on poor, sandy, or gravelly soils, where few other plants will grow. The best method of raising these hedges is, to sow the seed about the latter end of March, or the beginning of April, in the place where the hedge is designed; for the plants will not bear to be transplanted, unless it be done while they are young, and then there is great hazard of their taking. The ground where the seeds are to be sown should be well cleansed of weeds, and the surface made light; then there should be two or three drills made (according to the width which the hedge is intended) about half an inch deep, into which the seeds should be scattered pretty thick; and then the drills should be filled up with the head of a rake, to cover the seeds. This work should be performed in dry weather, for if much wet falls soon after the seeds are sown, it is apt to burst them. When the plants are come up, they should be kept clear from weeds, that they may spread and grow thick at bottom; and if these hedges are secured from cattle browsing on them, and are cut every spring just before they begin to shoot, they will make an exceeding close fence; but where they are designed to be cut for fuel, then the best way is to let them spread in width; and when they are two years old, to cut them down in the spring, just before they begin to shoot, within two or three inches of the ground, which will cause them to send forth a number of shoots from each root, and thereby increase the width of the hedge; and by so doing, the plants will not run up tall and weak, and be in danger of being weighed down by great falls of snow. These hedges when they are well grown, may be cut down every third or fourth year for fuel; wherefore if there is a treble row of Furz sown, at about three feet apart, they may be cut down alternately, so that there will be a fence always remaining. But this is only recommended for such sandy Lands as lett for a small rent, and where fuel is scarce. The best sort of Furz for this purpose is the greater kind, commonly called the French Furz, which will grow to eight or ten feet high, and is not apt to spread so much as the ordinary small sort.

Elder is sometimes planted for hedges, being very quick of growth; so that if sticks or truncheons about four or five feet long be thrust into a bank slopewise each way, so as to cross each other, and thereby form a sort of chequer work, it will make a fence for shelter in one year. But as this is a vigorous growing plant, it will never form a close fence; and the young shoots being very soft and pithy, are soon broken by cattle or boys in their sport. Besides, where they are suffered to bear berries, and these are scattered over the neighbouring Land, they will come up the following spring, and become very troublesome. Where these hedges are planted, they may be cut down every third year near the ground; and these stakes (when divested of their bark, so as to prevent their growing) will last longer in the ground, to support Vines or any other plants, which do not require tall stakes, than any other sort of tree yet known. And where the trees are suffered to grow to any considerable size, the wood is as hard as Box, and therefore very useful for turners and instrument makers. The best season for planting these truncheons is soon after Michaelmas, because the plants shoot very early in the spring. Of late years there have been many hedges, and other plantations, made of the white berried Elder, for the sake of their fruit to make wine; which, if rightly made, hath the flavour of Frontinac wine, and is by some persons mixed with white wines, and vended for it.

There

LAN

There are some other plants which have been recommended for fences, but those here enumerated are the most useful sorts for such purposes; wherefore I shall pass over the others, as not worthy of the care of the husbandman. And as to the farther directions for planting and preserving of hedges, with instructions for plashing or laying them, the reader is desired to turn to the articles of FENCES and HEDGES, where there are particular directions for these works exhibited, which I shall not here repeat.

The draining of Land is also another great improvement to it; for though meadows and pastures, which are capable of being overflowed, produce a greater quantity of herbage than dry Land, yet where the wet lies too long upon the ground, the Grass will be sour and extremely coarse; and where there is not care taken in time to drain this Land, it will produce little Grass, and soon be overrun with Rushes and Flags, so as to be of small value. The land which is most liable to this, is cold stiff clays where the water cannot penetrate, but is contained as in a dish; so that the wet which it receives in winter, continues till the heat of the sun exhales the greatest part of it.

The best method for draining of these Lands is, to cut several drains across the Land, in those places where the water is subject to lodge; and from these cross drains to make a convenient number of other drains, to carry off the water to either ponds or rivers in the lower parts of the Land. These drains need not be made very large, unless the ground be very low, and so situated as not to be near any river to which the water may be conveyed; in which case there should be large ditches dug at proper distances, in the lowest part of the ground, to contain the water; and the earth which comes out of the ditches should be equally spread on the Land, to raise the surface. But where the water can be conveniently carried off, the best method is, to make under ground drains at proper distances, which may empty themselves into large ditches, which are designed to carry off the water. These sort of drains are the most convenient, and as they are hid from the sight do not incommode the Land, nor is there any ground lost where these are made.

The usual method of making these drains, is to dig trenches, and fill the bottoms with stones, bricks, Rushes, or bushes, which are covered over with the earth which was dug out of the trenches; but this is not the best method, because the water has not a free passage through these drains, so that whenever there is a flood, these drains are often stopped by the soil which the water frequently brings down with it. The best method I have yet observed to make these drains, is to dig trenches to a proper depth for carrying off the water, which for the principal drains should be three feet wide at their top, and sloped down for two feet and a half depth, where there should be a small ledge or bank left on each side, upon which the cross stakes or bearers should be laid, and below these banks there should be an open drain left, at least one foot deep, and ten or eleven inches wide, that there may be room for the water to pass through. These larger drains should be at convenient distances, and smaller drains of about seven or eight inches wide at top, and the hollow under the bushes eight or nine inches deep, should be cut across the ground, which should discharge the water into these larger drains. The number and situation of them must be in proportion to the wetness of the Land; and the depth of the earth above the bushes, must also be proportioned to the intended use of the Land; for if it is arable Land to be ploughed, it must not be shallower than fourteen inches, that there may be sufficient depth for the plough, without disturbing the bushes; but for pasture Land, one foot deep will be full enough; for when the bushes lie too deep in strong Land, they will have little effect, the ground above will bind so hard as to detain the wet on the surface. When the drains are dug, there should be prepared a quantity of good brush wood, the larger sticks should

LAN

be cut out to pieces of about sixteen or eighteen inches in length, which should be laid across upon the two side banks of the drain, at about four inches distance; then cover these sticks with the smaller brush wood, Furz, Broom, Heath, or any other kind of brush, laying it lengthwise pretty close; on the top of these may be laid Rushes, Flags, &c. and then the earth laid on to cover the whole. These sort of drains will continue good for a great number of years, and are never liable to the inconveniencies of the other, for the water will find an easy passage through them; and where there is plenty of brush wood, they are made at an easy expence; but in places where wood is scarce, it would be chargeable to make them: however, in this case, it would be a great advantage to these Lands, to plant a sufficient number of cuttings of Willow, or the black Poplar, on some of the moist places, which would furnish brush wood for these purposes in four or five years; and as the expence of planting these cuttings is trifling, there cannot be a greater advantage to an estate which wants draining, than to practise this method, which is in every person's power, since there is little expence attending it.

In countries where there is plenty of stone, that is the best material for making these under ground drains; for when these are properly made, they will never want repairing.

The best time of the year for making these drains is about Michaelmas, before the heavy rains of autumn fall, because at this season the Land is usually dry, so that the drains may be dug to a proper depth; for when the ground is wet, it will be very difficult to dig to any depth, because the water will drain in wherever there is an opening in the ground.

When these drains are made, and the water carried off the Land, it will be proper to pare off the Rushes, Flags, &c. which may be laid in heaps in proper places to rot, and will afford a good manure for the land. The ground must also be ploughed to destroy the roots of noxious weeds, and if it be laid fallow for one season, and ploughed two or three times, it will greatly mend the Land. The Rushes and Flags which were pared off the ground when rotten, should be spread over the surface, and the Grass-seed sown thereon, which will greatly forward the Grass, so that it may soon be brought to a good turf; which Land thus mended, has been lett for four times the rent it was set at before.

There are some persons, who, after they have pared off the Flags, Rushes, &c. from their Land, lay them in small heaps, and burn them in dry weather, then spread the ashes on the Land to improve it, which is a good method, where a person is in haste to have Grass again; but where the ground can be fallowed one year, it will loosen the soil, and more effectually destroy the roots of all noxious weeds; and the Rushes, &c. when rotted, will afford a much larger quantity of manure for the Land than when it is burnt: besides, this can only be practised in the summer season, when the weather is very dry; for if there should fall much rain, the fires will go out, and it will be impracticable to burn it. But where the method of burning is practised, the heaps should not be too great, and it should burn very slowly; which will render the ashes a much better manure, than when the fire is too violent, or the heaps too large; for in this case, the inner part will be over-burnt before the fire reaches the outside of the heap.

As the draining of cold wet Lands is a great improvement to them, so the floating or watering of dry loose Land is not a less advantage to them. This may be easily effected where there are rivers, or reservoirs of water, which are situated above the level of the ground designed to be floated, by under ground drains (made after the manner of those before directed for draining of Land,) through which the water may be conveyed at proper seasons, and let out on the ground: in order to this, there must be good sluices made at the heads of the drains, so that the water may never get out, but at such times as is required;

for

LAN

for if this be not taken care of, the water, instead of improving the Land, will greatly damage it.

But where the Land lies so high, as that there is no water in the neighbourhood lying above its level, it will be more expensive; because in such case, the water must be raised by machines, from reservoirs or streams which lie below it. The most common engine used for this purpose is the Persian wheel (which, being well described and figured in Woolridge's Art of Husbandry, is needless for me here to repeat.) Yet notwithstanding the expence of raising the water, it has been found greatly advantageous in many parts of England, to drown the Lands, for the profit has many times more than doubled the charge.

The time for drowning of Land, is usually from November till the end of April; but though this is the general practice, yet I cannot approve of it for many reasons. The first is, that by the wet lying continually on the ground in winter, the roots of the finer sort of Grass are rotted and destroyed; and by letting on the water, at the season when the seeds of Docks, and other bad weeds, which commonly grow by river sides, are falling, these seeds are carried upon the Land, where they remain and grow, and fill the ground with bad weeds, which is commonly the case with most of the water meadows in England, the Grass in general being destroyed; so that Rushes, Docks, and other trumpery, make up the burden of these Lands: but if these meadows were judiciously managed, and never floated till March or April, the quantity of sweet good Grass would be thereby greatly increased, and the beautiful verdure of the meadows preserved: but there is little hope of convincing those persons by any arguments, who are so much wedded to their own prejudices, as to shut their eyes and ears against experiments or reason. Where the Land is very hot and dry, and it lieth convenient to be watered at a small expence, it should be repeated every week in dry hot weather, which will prove a great advantage to the Land. But whenever this is done, there should no cattle be admitted while it is wet, for they will poach, and spoil the turf.

Another great improvement of Land, is by burning of it, which, for four, heathy, and rushy Land, be it either hot or cold, wet or dry, is a very great improvement; so that such Lands will, in two or three years after burning, yield more, exclusive of the charges, than the inheritance was worth before; but this is not to be practised on rich fertile Land; for as the fire destroys the acid juice, which occasions sterility in the poor Land, so it will in like manner consume the good juices of the richer Land, and thereby impoverish it, so that it hath been with great reason diffused in deep rich countries.

The usual method of burning Land is, to pare off the turf with a breast plough, turning it over as it is cut, that it may dry the better. And if it proves hot dry weather when this work is done, then it needs no more turning; but if rain should fall, it must be turned, and the turfs set a little hollow, that they may dry the better; and when they are thorough dry, they may be laid on small heaps, about half a cart load on a heap, or less, for the smaller the heaps are, provided there is quantity enough to make a good fire, so as to consume the whole to ashes, it is the better; if the turf be full of fibrous roots, or hath much Moss or Fern on it, it will burn without any additional fuel; but if it hath not, the heaps should be raised on small bundles of Heath, Fern, Gorze, &c. which will set the whole on fire; yet there should be no more of these things applied, than what is necessary to kindle the fire, because the slower the turf consumes, the better will be the ashes. When the turf is wholly consumed, the ashes should be equally scattered over the ground in a calm day, lest the wind should drive it in heaps. Then the Land should be gently ploughed, and the seeds sown thereon; for if the ground is ploughed too deep, the ashes will be buried too low for the roots of the Grass or Corn to reach them for a considerable time; nor should the

LAN

ashes lie too near the surface, because then the roots will reach them too soon, and the strength of the ashes will be spent to nourish only the blade, so that the Corn will grow too rank in winter; and when the roots in the spring strike down lower, they will meet with a poorer soil, nor will the stalks and ears have so much advantage from the improvement, as the useless blade. But when care is taken in this particular, it is wonderful what success it hath; for by this method the poorest plains, and four heathy Lands, have been rendered as fertile as almost any good cultivated ground whatever.

It is also a very great improvement, where Land is overgrown with Broom, Furz, &c. to stub them up by the roots, and when they are dry, lay them on heaps, and cover them with the parings of the earth, and burn them, and spread the ashes over the ground. By this method vast tracts of Land, which at present produce little or nothing to their owners, might be made good at a small expence, so as to become good estates to the proprietors.

There are several other methods of improving Land beside those here mentioned, as by planting of wood, or adapting the several sorts of plants to the particular soils with which they agree; but as most of these things are treated of under the several articles where these plants are mentioned, I shall forbear to repeat them in this place, but shall beg leave to offer a few general hints on the present situation of the Lands in England, which may probably excite some abler hand to undertake a fuller and more complete disquisition of this subject.

For some years past, the quantity of Corn raised in England, has greatly exceeded the consumption, so that great quantities of Corn have been exported, by which great sums of money have been brought into England; but this was accidental; for had not the crops failed in the neighbouring countries, there would have been no demand for the produce of England, so that the quantity here grown must have reduced the price so low, as to have almost ruined the farming interest; nor is it possible to contrive any scheme, in a country circumstanced as this, whereby the public may not, at times, suffer from the extravagant price, which, in a scarcity, this commodity may be raised to; or, on the other hand, the farmers are sometimes almost undone by the low price which it is often reduced to in times of plenty; and surely there can be no one thing more worthy of the serious attention of every person, who has the least regard for the public welfare, than this, of always making such provision of Corn, against accidental scarcities, as that the inhabitants may never be distressed for want of the staff of life, or the price be so high, as that the common people cannot purchase it. If I am not greatly mistaken, there has been, within the space of three or four years, such a disproportion in the price of Corn, as can hardly be conceived, and this within the memory of numbers of persons; the time I mean is between 1705 and 1709, in the compass of which time the peck loaf of fine bread was risen from fourteen pence to four shillings and twopence; the low price of this commodity was as detrimental to the farmers, as the extravagant price was afterward to the public, neither of which would have so severely felt the effects, had there been public granaries where the Corn might have been deposited, and this purchased from the farmer, at a price by which he might live, at the public expence, and sold out again at an easy rate in times of scarcity; but I fear this is not an age for encouraging any scheme for public utility, when in every thing of this kind, however beneficial it may be to the country, and though proposed as such to the public, if it meets with any reception, it is with a view to turn it to private interest; the practice of turning all things into private jobs, has so much prevailed of late years, as to have almost extinguished every social

virtue;

virtue; but I fear I may have incurred the censure of many for this digression; but, be it as it will, I could not omit it, when it so properly came in my way; and as it is from a sincere love and regard to my country, that I have mentioned this, so it may be hoped, that if any harsh expression has been used, it will be forgiven. But to return to my subject; as the quantity of Land now in tillage is very great in England, from the destruction of woods, the ploughing up of downs, the inclosing of commons, &c. so that, unless there happens a failure in the crops of Corn in great part of England, the markets must be so low, as that the farmer will always find it difficult to support his family, and pay his rent; the first must be done, let the landlord fare as he will, for the farmers know, that when the farms are occupied by the landlords, few of them can make the produce of the Land and pay their expence, so that the whole rent of the farm is often sunk, beside the trouble and fatigue of managing the farms; and it is greatly to be feared, from the present condition of the farmers in general, that many landlords will be obliged to undertake this disagreeable affair, which will be the more so, as their Lands will be left without stock, and the soil exhausted, and overgrown with weeds, which will require some years to put into proper condition, and will be attended with great expence.

The extraordinary price which Corn bore some years since, tempted the farmers to break up the downs in many parts of England; and the landlords were brought to comply with the request of the farmer, for the sake of a little advance of the rent, not considering the future consequence of it; so that hereby great extents of downs have been ruined, and not likely to be recovered again; for the soil in many places was not more than four or five inches deep, upon beds of flint or chalk, which, in ploughing, were turned up on the surface, and the little soil which covered them, was in a few years so much exhausted, as not to produce the quantity of grain which was sown upon them; and as there was no probability of procuring dressing for the Lands, the farmers have been obliged to throw them up, which now lie waste, and appear like quarries of flints, or beds of chalk, without Grass, or almost any other plant growing upon them. By this passion for ploughing, the farmers have lessened their stock of cattle, and, of consequence, their quantity of manure has been lessened in proportion, so that they have either been obliged to purchase dressing at a great expence, or destroy their Lands of their vegetative quality: by the former method, when grain bears a low price, the farmer is ruined, and by the latter, every one must know what will be the consequence to both tenant and landlord; therefore it is a matter of great concern to the proprietors of Lands, to see that no more ground in their farms is kept in tillage, than the tenant can supply with dressing, so as to maintain the Land in heart; and that a proper stock of cattle be kept up, in proportion to the size of the farms, which cannot be done where there is not a proportion of pasture kept to that of the arable Land in each farm. There are many persons, who, by a mistake in the article of inclosing Lands, are likely to fall into a great error, by supposing, that the inclosing of commons will be a great advantage to their estates, and perhaps there may be tenants on their estates, who may encourage the gentlemen so to do, from a present interest of their own; but wherever this has been done, the estates have soon fallen in their rents, much lower than the addition made by inclosing the commons, which must always be the case; for if there is not common pasture, where the farmers can turn out their cattle in summer, it cannot be supposed they can keep up a stock of live cattle upon their inclosed pasture; so that, although the dividing and inclosing the Lands in the common fields would be a very great benefit, yet the destroying of pasture commons would on the other extreme be a national disadvantage and loss. There

are many other particulars, which might be here enumerated, to shew the cause of the low condition of the farmers in general; but these few hints may probably lead some persons of abler heads to the consideration of this affair, so I shall not enlarge upon them here.

LANIGEROUS TREES are such as bear a woolly or downy substance, as is commonly contained in the katkins of Willows, &c.

LANTANA. Lin. Gen. Plant. 683. Camara. Plum. Nov. Gen. 32. tab. 2. American Viburnum, or Camara.

The CHARACTERS are,

The empalement of the flower is cut into four segments. The flower is monopetalous, of an irregular shape, having a cylindrical tube, which extends beyond the empalement, and is spread open at the brim, where it is divided into five segments. In the center of the flower is situated the pointal, supporting a crooked stigma, attended by four stamina, two being longer than the other. The pointal afterward changes to a roundish fruit, opening into two cells, and inclosing a roundish seed.

This genus of plants is ranged in the second section of Linnæus's fourteenth class, intitled Didynamia Angiospermia, which includes those plants whose flowers have two long and two shorter stamina, and the seeds are inclosed in the capsule.

The SPECIES are,

1. **LANTANA** (*Aculeata*) foliis oppositis, caule aculeato ramoso, floribus capitato-umbellatis. Lin. Sp. 874. *Lantana with leaves growing opposite, a branching prickly stalk, and umbellated flowers growing in heads.* Viburnum Americanum odoratum, urticæ foliis latioribus spinosum, floribus miniatis. Pluk. Alm. 285. tab. 223. *Sweet prickly American Viburnum, with broad Nettles leaves, and carmine flowers.*
2. **LANTANA** (*Inermis*) caule inermi, foliis lanceolatis dentatis alternis, floribus corymbosis. *Lantana with a smooth stalk, spear-shaped indented leaves placed alternate, and flowers growing in round bunches.* Periclymenum rectum, salviæ foliis majoribus oblongis, mucronatis, subtus villosis, alternatim sitis, flore & fructu minoribus. Sloan. Cat. Jam. 164. *Upright Honeysuckle with larger, oblong, acute-pointed Sage leaves, which are hairy on their under side, placed alternate, and a smaller flower and fruit.*
3. **LANTANA** (*Lanuginosa*) caule ramoso lanuginoso, foliis orbiculatis crenatis oppositis, floribus capitatis. *Lantana with a hairy branching stalk, round crenated leaves placed opposite, and flowers collected in heads.* Periclymenum rectum, salviæ folio rugoso minore, subrotundo. Cat. Jam. 164. *Upright Honeysuckle with a smaller rough roundish leaf.*
4. **LANTANA** (*Trifolia*) foliis ternis, caule inermi spicis oblongis imbricatis. Lin. Sp. Plant. 873. *Lantana with leaves placed by threes round the stalk, without spines, and oblong imbricated spikes of flowers.* Camara trifolia, purpurascens flore. Plum. Nov. Gen. 32. *Three-leaved Camara, with a purplish flower.*
5. **LANTANA** (*Urticæfolia*) caule aculeato, foliis oblongo-cordatis serratis oppositis, floribus corymbosis. *Lantana with a prickly stalk, oblong, heart-shaped sawed leaves, and flowers growing in a corymbus.* Periclymenum rectum urticæ folio hirsuto majore, flore flavo. Sloan. Cat. Jam. 163. *Upright Honeysuckle with a larger Nettles leaf, and a yellow flower.*
6. **LANTANA** (*Camara*) caule inermi, foliis ovato-lanceolatis, serratis, rugosis, floribus capitatis lanuginosis. *Lantana with a smooth stalk, oval, spear-shaped, rough, sawed leaves, and flowers growing in woolly heads.* Periclymenum rectum, salviæ folio rugoso, majore, subrotundo & bullato. Sloan. Cat. Jam. 163. *Upright Honeysuckle with a large, rough, Sage leaf, which is roundish and fluted.*
7. **LANTANA** (*Bullata*) foliis oblongo-ovatis acumina- tis serratis rugosis alternis, floribus capitatis. *Lantana with oblong, oval-pointed, sawed leaves, which are rough, placed alternate, and flowers growing in heads.* Periclymenum rectum, salviæ folio rugoso, minore, bullato, flore

flore albo. Sloan. Cat. 163. *Upright Honeysuckle with a smaller rough Sage leaf, which is studded, and a white flower.*

8. LANTANA (*Alba*) caule inermi, foliis ovatis serratis, floribus capitatis alaribus sessilibus. *Lantana with a smooth stalk, oval sawed leaves, and flowers growing in heads proceeding from the wings of the leaves, sitting close to the stalks.* Camara foliis urticæ, floribus minoribus albis, ex alis foliorum prodeuntibus. Houst. *Camara with a Nettle leaf, and smaller white flowers proceeding from the wings of the leaves.*
9. LANTANA (*Annua*) foliis quaternis, caule aspero, spicis oblongis. *Four-leaved Lantana with a rough stalk, and oblong spikes of flowers.* Periclymenum rectum humilissimum, folio rugoso majore, flore purpureo, fructu oblongo, esculento purpureo. Sloan. Cat. Jam. 164. *Lower upright Honeysuckle with a larger rough leaf, a purple flower, and an oblong, purple, esculent fruit.*
10. LANTANA (*Angustifolia*) caule inermi, foliis ovato-lanceolatis oppositis, floribus capitatis pedunculis longissimis. *Lantana with a smooth stalk, oval spear-shaped leaves placed opposite, flowers collected in heads, and very long foot-stalks.* Periclymenum rectum, salviæ folio rugoso, longo & angustissimo. Sloan. Cat. 164. *Upright Honeysuckle with a rough Sage leaf, which is long and narrow.*
11. LANTANA (*Africana*) foliis alternis sessilibus, floribus solitariis. Hort. Cliff. 320. *Lantana with alternate leaves sitting close to the stalks, and flowers growing singly.* Jasminum Africanum, illicis folio, flore solitario ex foliorum alis proveniente albo. Com. Plant. Rar. 6. tab. 6. *African Jasmine with an Ilex leaf, and a solitary white flower coming from the wing of the leaves.*
12. LANTANA (*Salvifolia*) foliis oppositis sessilibus, floribus racemosis. Lin. Sp. 875. *Lantana with leaves placed opposite close to the stalks, and flowers in a racemus.* Frutex Africanus, foliis conjugatis salviæ angustis, floribus hirsutis. Herm. Afr. 10.

The first sort is pretty common in those English gardens, where there are collections of exotic plants; this grows naturally in Jamaica, and most of the other islands in the West-Indies, where it is called wild Sage, as are several of the other sorts which are not distinguished by the inhabitants. It rises with a woody stalk five or six feet high, sending out many branches, which have four angles, armed with short crooked spines. The leaves are placed opposite; they are oval, spear-shaped, about an inch and a half long, and three quarters of an inch broad, hairy, and stand upon short foot-stalks; toward the end of the branches the flowers come out from the wings of the stalks, two foot-stalks arising from the same joint, one on each side; they are near two inches long, and are terminated by roundish heads of flowers, those which are on the outside and form the border, are first of a bright red, or scarlet colour; these change to a deep purple before they fall. Those flowers which are in the center are of a bright yellow, but after some time fade to an Orange colour. The flowers are succeeded by roundish berries, which, when ripe, turn black, having a pulpy covering over a single hard seed. This plant in the West-Indies continues to flower most part of the year; but in England they begin to flower in June, and continue in succession till near Christmas, and the early flowers are succeeded by ripe seeds.

The second sort grows naturally in Jamaica; this rises with a slender, smooth, shrubby stalk, about four feet high, dividing into many small quadrangular branches which grow erect, garnished with spear-shaped leaves about two inches long, and one inch broad, indented on their edges, and hoary on their under side, standing alternate upon short foot-stalks. Toward the end of the branches the foot-stalks of the flowers arise alternately from the wings of the leaves; these are very slender, and support small heads of pale purple flowers, which are succeeded by small purple berries, each having one seed. This flowers at the same time with the former sort. The seeds of this sort were first sent me by the late Dr. Houstoun, from La Vera

Cruz, but I have since received them from Jamaica.

The third sort was sent me from La Vera Cruz, by the late Dr. Houstoun; this rises with a shrubby stalk about three feet high, dividing into several upright branches. The leaves are oblong, and sawed on their edges, standing opposite, on the lower part of the branches, but toward the upper part they are placed by threes round the branches. The foot-stalks of the flowers come out from the wings of the leaves; they are near three inches long, sustaining an oblong spike of purple flowers, which come out from imbricated scales, which end in acute points. The flowers are succeeded by pretty large purple berries. This flowers at the same time with the former sorts.

The seeds of the fourth sort were sent me from the Havanna, by the late Dr. Houstoun; this rises with a shrubby stalk about three feet high, covered with a gray bark, which is woolly. It divides into branches by pairs, which are garnished with round leaves, indented on their edges, whose upper surface is corrugated and rough, like those of Sage; they are placed opposite, standing upon short foot-stalks. At the end of the branches arise the foot-stalks of the flowers, which are short, and sustain a globular head of purple flowers; these are succeeded by pretty large purple berries containing one seed. This flowers at the same time with the former sorts.

There is a variety of this with white flowers, whose leaves are not quite so round, nor are they crenated on their edges; but I suspect they both come from the same seeds, so I have not enumerated it as a distinct species.

The fifth sort was sent me from La Vera Cruz, by the late Dr. Houstoun; this rises with a woody branching stalk four or five feet high, garnished with oblong heart-shaped leaves, which are sawed on their edges, and end in acute points. At the end of the branches the flowers come out in round bunches, standing upon slender upright foot-stalks, about one inch long. The flowers are yellow, and grow in looser bunches or heads than those of the former sorts, but flowers at the same time.

The sixth sort rises with a woody branching stalk five or six feet high, covered with a dark brown bark. The branches are more divided than those of the other sorts, and are much more ligneous. The leaves are two inches and a half long, and one inch and a quarter broad, deeply sawed on their edges, and their upper surface very rough, and many of them closely set with white prominent spots as if studded; these are placed alternately on the branches. The flowers come out from the wings of the stalk, standing upon pretty long foot-stalks; they are white, and are collected in small woolly heads. This flowers about the same time with the former sorts.

The seventh sort rises with a branching shrubby stalk about four feet high, covered with a dark brown bark, and garnished with small, oblong, oval leaves, ending in acute points; they are an inch long, and half an inch broad, very much veined on their upper side, standing alternately pretty close to the branches. The flowers come out at the end of the branches upon short foot-stalks, in close small heads; these are white, and make but little appearance. It flowers at the same time with the former.

The eighth sort was sent me by the late Dr. Houstoun, from Campeachy; this hath a slender shrubby stalk which rises three or four feet high, dividing into many slender, smooth, square branches, which are garnished with small, oval, sawed leaves placed opposite; from the wings of the stalk, at every joint, come out the flowers; they are small, white, and are collected in close heads; these come out by pairs, and sit close to the branches. This flowers at the same time with the former.

The ninth sort is annual; this was first sent me by the late Dr. Houstoun from La Vera Cruz, but I have since received the seeds from the north side of the island of Jamaica; it rises with a strong, upright,

rough

L A N

rough stalk near three feet high, dividing toward the top into two or three erect branches, which are garnished with oblong, oval, sawed leaves, ending in acute points; they are placed by fours at each joint, and are a little woolly on their under side. The flower-stalks arise by pairs, and sometimes three come out at the same joint; they are from two to three inches long, and sustain a thick spike of large purple flowers, which are succeeded by large purple berries that are very succulent, and are frequently eaten by the inhabitants. This sort flowers in July, provided the plants are raised early in the spring and brought forward, and the seeds will ripen in autumn, soon after which the plants decay.

The tenth sort grows naturally in Jamaica, from whence the late Dr. Houstoun sent me the seeds; this rises with a slender, smooth, branching stalk three feet high. The branches are garnished with oval spear-shaped leaves two inches long, and one inch broad; they are crenated on their edges, and rough on their upper side, standing by pairs opposite, upon very short foot-stalks, having an agreeable odour. The flowers come out from the wings of the stalk, upon very long foot-stalks; they are placed opposite the whole length of the young branches, sustaining small round heads of white flowers; these appear at the same time with the other sorts, but rarely produce seeds in England.

These plants are all of them easily propagated by cuttings except the ninth, which is an annual plant, so can only be propagated by seeds. They may also be propagated by seeds, which several of the sorts produce in England, and the others may be easily procured from the West-Indies, where there are a greater variety of these plants growing naturally, than are at present known in Europe; they are all of them called Wild Sage, by the inhabitants of the British Islands, but they do not distinguish the sorts. These seeds should be sown in pots filled with light earth, and plunged into a hot-bed of tan; the reason for my advising them to be sown in pots, is, because the seeds frequently remain long in the ground before they vegetate; therefore if the plants should not come up the same year, the pots should be placed in the stove in winter, and the following spring plunged into a new hot-bed, which will bring up the plants. When these are fit to remove they should be each planted in a small pot, and plunged into another hot-bed, observing to shade them till they have taken new root; then they should have air admitted to them every day, in proportion to the warmth of the season, to prevent their being drawn up with weak stalks; afterward they must be treated in the same manner as other plants from the same country, till they have obtained strength; then they may be removed into an airy glass-case, or a dry stove, where they may have a large share of air in warm weather, but protected from the cold. This is necessary for the young plants, which should not the first year be exposed to the open air, but afterward they may be placed abroad in the warmest part of summer, and in winter placed upon stands in the dry stove, where they will continue long in flower, and many of the sorts will ripen their seeds; but in winter they should be sparingly watered, for much moisture will rot their roots.

If they are propagated by cuttings, the best time for planting them is in July, after the plants have been exposed to the open air for about a month, by which time the shoots will be hardened so as to be out of danger of rotting with a little moisture. These cuttings should be planted in small pots filled with light earth, and plunged into a moderate hot-bed; and if they are screened from the violence of the sun in the middle of the day, they will be rooted in about six weeks time, when they must be hardened gradually to bear the open air, and afterward treated as the old plants.

The eleventh sort has been long in the English gardens, and is commonly called the Ilex-leaved Jasmine. This sort rises with a shrubby stalk five or six feet high,

L A P

sending out many irregular branches, which are closely garnished with thin oval leaves ending in points, and sawed on their edges, which embrace the branches with their base, and from the bosom of each leaf comes out one solitary white flower, which is cut at the top into five parts, and at first sight has the appearance of a Jasmine flower; but when closer viewed, the tube will be found curved in the same manner with those which Dr. Linnæus titles ringent flowers. The flowers are not succeeded by seeds in England, but the plants are easily propagated by cuttings, which, if planted upon an old hot-bed any time in July, and covered with a bell or hand-glass, and shaded from the sun, will put out roots in a month or five weeks; then they may be planted in pots, and placed in the shade till they have taken fresh root; after which they may be removed to a sheltered situation, where they may remain till the frosts come on. This plant was brought from the Cape of Good Hope, so is not very tender, therefore may be preserved in a good greenhouse in winter; but during that season it must have a large share of air in mild weather, otherwise it is apt to grow mouldy, and this will cause the tender branches to decay. In the summer season it may be exposed in the open air, with other greenhouse plants, in a sheltered situation, where it will add to the variety; and although the flowers are small, and are produced singly from between the leaves, so do not make any great appearance; yet as there is a succession of these flowers most part of the year, and the leaves continuing green throughout the year, it is rendered worthy of a place in every collection of plants.

The last sort is a native of Africa; this rises with a shrubby four-cornered stalk eight or ten feet high, covered with a pale loose bark, sending out many side branches, garnished with rough leaves five or six inches long, whose base embrace the stalks, but they end with sharp points, and are downy on their under side; the branches are terminated by loose spikes of pale purple flowers, covered with a mealy down; these appear in summer, but are rarely succeeded by seeds in England.

This is propagated by cuttings in the same manner as the eleventh sort, and the plants require the same treatment.

L A N U G I N O U S, signifies downy, or to be covered with a soft down, as a Quince.

L A P A T H U M. See **RUMEX**.

L A P S A N A. Lin. Gen. Plant. 823. *Lampsana* & *Rhagadiolus*. Tourn. Inst. R. H. 479. tab. 272. *Nipplewort*.

The CHARACTERS are,

The flower is composed of several hermaphrodite florets, which are included in one common imbricated empalement. The florets have one petal, which is tubulous and stretched out at the top, in shape of a tongue; these have each five short hairy stamina, terminated by cylindrical summits which coalesce. The germen is situated at the bottom of the floret, supporting a slender style, crowned by a reflexed bifid stigma; the germen afterward becomes an oblong three-cornered seed, situated in the scale of the empalement.

This genus of plants is ranged in the first section of Linnæus's nineteenth class, intitled *Syngenesia Polygamia Æqualis*, in which he ranges those plants with hermaphrodite flowers which are fruitful, whose stamina and style are connected together; and to this genus he has joined the *Rhagadiolus* and *Zacintha* of Tournefort, making them only species of the same genus.

The SPECIES are,

1. **LAPSANA** (*Communis*) calycibus fructus angulatis, pedunculis tenuibus ramosissimis. Hort. Cliff. 384. *Nipplewort with angular empalements to the fruit, and very narrow branching foot-stalks.* *Lampsana*. Dod. p. 675. *Common Nipplewort.*
2. **LAPSANA** (*Rhagadiolus*) calycibus fructus undique patentibus, radiis subulatis, foliis lyratis. Hort. Upsal. 245. *Nipplewort with empalements to the fruit spreading open every way, awl-shaped rays, and spear-shaped undivided*

vided leaves. Rhagadiolus alter. Cæfalp. 511. Another Rhagadiolus.

3. LAPSANA (*Lampsanæfoliis*) calycibus fructus undique patentibus, radiis subulatis, foliis lyratis. Hort. Upsal. 245. Nipplewort with empalements to the fruit spreading open every way, awl-shaped rays, and barp-shaped leaves. Rhagadiolus Lamplanæ foliis. Tourn. Cor. 36. Rhagadiolus with a Nipplewort leaf.

4. LAPSANA (*Zacintha*) calycibus fructus torulosis depressis obtusis sessilibus. Lin. Sp. Plant. 811. Nipplewort with a depressed knotted empalement which is obtuse, and sits close to the branches. Zacintha five cichorium verrucarium. Tourn. Inst. 476. Zacintha, or warted Cichory.

The first sort is a common weed, which grows by the side of foot-paths and hedges in most parts of England, so is not permitted to have room in gardens.

The second and third sorts grow naturally in Portugal, from whence I have received their seeds. These are annual plants, of no beauty or use, but are preserved in botanic gardens for the sake of variety. If the seeds of these are permitted to scatter, the plants will come up without trouble, and two or three of them will be enough to leave to keep the sorts.

The fourth sort grows naturally in Italy; this is also an annual plant, of neither use or beauty, but is like the others kept for variety. If the seeds of this sort scatter in the autumn, the plants will come up better than if sown in the spring. The plants require no culture, but will thrive like weeds.

- I. A R I X. Tourn. Inst. R. H. 586. tab. 353. Pinus. Lin. Gen. Plant. 956. The Larch-tree; in French, *Melèze*.

The CHARACTERS are,

It hath male and female flowers growing separate on the same tree. The male flowers are disposed in a scaly katkin; these have no petal, but a great number of stamina which are connected in a column below, but are separated at their points, and are terminated by erect summits. The female flowers are disposed in a conical shape, having no petals; these are placed by pairs under each scale, having a small germen, supporting an awl-shaped style, crowned by a single stigma. The germen afterward becomes a nut with a membranous wing, inclosed in the scales of the cones.

This genus of plants is ranged in the ninth section of Linnæus's twenty-first class, intitled Monœcia Monodelphia, the same tree having male and female flowers in different parts, and the stamina of the male flowers are united in one cluster. Dr. Linnæus has joined this genus, and the Abies of Tournefort, to the genus of Pinus, which, according to his system, may very well be brought together; but as Tournefort and all former botanists have separated them by the form of their leaves, those of the Abies coming out single from the branches, those of the Pine coming out by two, three, or five out of each sheath, and those of this genus arising in clusters in the bottom, but are spread above like a painter's pencil, so these distinctions being pretty generally known by gardeners, I have chosen to continue them under their former separate titles to prevent confusion.

The SPECIES are,

1. LARIX (*Decidua*) foliis deciduis, conis ovatis obtusis. Larch-tree with deciduous leaves, and oval obtuse cones. Larix folio deciduo, conifera. J. B. 1. p. 265. Common Cone-bearing Larch-tree.
2. LARIX (*Chinensis*) foliis deciduis, conis mucronatis squamis acutis. Larch-tree with deciduous leaves, and pointed cones having acute scales.
3. LARIX (*Cedrus*) foliis acutis perennantibus, conis obtusis. Larch-tree with acute evergreen leaves and obtuse cones. Cedrus conifera, foliis laricis. C. B. P. 490. Cone-bearing Cedar with a Larch-tree leaf, or the Cedar of Lebanon.

The first sort grows naturally upon the Alps and Apennines, and of late years has been very much propagated in England. This tree is of quick growth, and will rise to the height of fifty feet; the branches are slender, and their ends generally hang downward. These are garnished with long narrow leaves, which

arise in clusters from one point, and spread open above like the hairs of a painter's brush; they are of a light green, and fall away in autumn like other deciduous trees. In the month of April the male flowers appear, which are disposed in form of small cones; the female flowers are collected into oval obtuse cones, which in some species have bright purple tops, and in others they are white: these differences are accidental, for I have found the seeds taken from either of these varieties, will produce plants of both sorts; the cones are about one inch long, obtuse at their points, and the scales lie over each other, and are smooth; under each scale there is generally lodged two seeds which have wings.

There are two other varieties of this tree, one of which is a native of America, and the other of Siberia; the latter requires a colder climate than England, for they are very apt to die in summer here, especially if they are planted on a dry soil. The cones of this sort which have been brought to England, seem to be in general larger than those of the common kind; but there is so little difference between the trees in their characteristic notes, as not to be distinguished as different species, though by the growth of the trees there is a remarkable difference.

The cones of the second sort were sent from China, to the Right Hon. the Earl of Northumberland, who was so good as to communicate some of the seeds to me, which were sown in the Chelsea garden, where they succeeded, as they also did in his Lordship's garden at Stanwick. The cones of this sort were much larger than those of the common sort, and ended in acute points; the scales were prominent like those of the Scotch Pine, and had so little resemblance to those of the Larch, as that every one who saw them, imagined they were a sort of Pine; they were titled, Fir good to keep up banks. As these plants make but little progress the first year, so they were weak, and in the autumn casting off their leaves, they were supposed to be dead, and most of the plants were thereby lost; but those which escaped, afterward shot their branches out horizontally, spreading close to the ground, and by their present appearance, seem to be a shrub which never will rise upright. This sort is so hardy, as to thrive in the open air without any protection.

The common Larch is now very plenty in most of the nurseries in England, and of late years there has been great numbers of the trees planted; but those which have been planted in the worst soil and in bad situations, have thriven the best; for where trees of equal size have been planted in good garden earth at the same time, the others on the cold stiff land, have in twelve years been twice the height of those planted in good ground; which is an encouragement to plant these trees, since they will thrive in the most exposed situations, provided they are planted in clumps near each other, and not single trees; nor should the plants which are planted in very open exposed places be taken from warm nurseries, but rather raised as near to the spot where they are to remain as possible; nor should the plants be more than three or four years growth when planted, where they are designed to grow large; for though trees of greater size will remove very well, and grow several years as well as if they had not been transplanted; yet after twenty or thirty years growth they will frequently fail, where the young planted trees have continued very vigorous.

These trees are raised from seeds, which most years ripen well in England: the cones should be gathered about the end of November, and kept in a dry place till the spring, when they should be spread on a cloth and exposed to the sun, or laid before a fire, which will cause the scales of the cones to open and emit their seeds. These seeds should be sown on a border, exposed to the east, where the morning sun only comes on it; or if they are sown on a bed more exposed to the sun, they should be screened with mats from the sun in the middle of the day; for when the plants first appear above ground, they are very impatient of heat; and

L A R

and when the bed is much exposed to the sun, the surface of the ground will dry so fast, as to require to have water very often, which frequently rots the tender stems of the plants; which will be prevented by properly shading them while young, and afterward they will be in no danger. These young plants should be constantly kept clean from weeds, and if they have made good progress, they may be transplanted the following autumn, otherwise they may remain in the seed-bed another year, especially if the plants are not too close together. When they are transplanted, it should be performed in the autumn as soon as their leaves decay; they may be planted in beds at about six inches asunder each way, which will be distance enough for the growth of the plants the two following years, by which time they will be fit to transplant where they are to remain.

When the young trees are planted out for good, they need not be more than eight or ten feet distant from each other, always planting them closer on exposed situations, than where they are more defended; after the trees are planted, they will require no other care but to keep them clean from weeds for three or four years till the trees have obtained strength, when they will over-top the weeds and prevent their growth; but the ground between these trees should not be dug, for that I have found has greatly stopped their growth.

The Siberian Larch is of slow growth in this country, for when the spring is mild, the trees will begin to shoot in February, or early in March; and there are frequently sharp frosts after, whereby these shoots are often killed, and this stops the growth of the trees. Likewise when they are planted on a warm dry soil, they are frequently killed by drought in the summer; therefore this is a very improper tree for this country, unless for some cold, moist, peaty land, where they may probably thrive, and in such situations few other trees will grow.

The American or black Larch, thrives pretty well upon moist land, but on dry ground will make but little progress. A few of these trees by way of variety, may be allowed to have place in every collection of trees designed for pleasure; but for profit, the common Larch is to be preferred to any other species.

In Switzerland, where these trees abound, and they have a scarcity of other wood, they build most of their houses with it; and great part of their furniture is also made of the wood, some of which is white, and some red, but the latter is most esteemed. The redness of the wood is by some supposed to be from the age of the trees, and not from any difference between them, but is rather owing to the quantity of turpentine contained in them. They frequently cut out the boards into shingles of a foot square, with which they cover their houses, instead of tiles or other covering; these are at first very white, but after they have been two or three years exposed, become as black as charcoal; and all the joints are stopped by the resin, which the sun draws out from the pores of the wood, which is hardened by the air, and becomes a smooth shining varnish, which renders the houses so covered impenetrable to either wind or rain; but as this is very combustible, the magistrates have made an order of police, that the houses so covered should be built at a distance from each other to prevent fire, which has often done great damage in villages.

In most countries where this wood is in plenty, it is preferred to all the kinds of Fir for every purpose; and in many places there are ships built of this wood, which they say are durable; therefore this may be a very proper tree for planting upon some of the cold barren hills in many parts of England, which at present produce nothing to their proprietors, and in one age may be large estates to their posterity, and a national advantage; which might be effected without a great expence, where the business is properly conducted.

The best method for doing this, would be by making small nurseries on or near the place where the plan-

L A R

tation is intended to be made, in those nurseries the seeds should be sown; and if there are any poor cottagers there, these may be employed in raising of the plants, keeping of them clean, and afterward in transplanting them. This will lessen the number of indigent poor, and by employing them in this sort of husbandry, they may be brought to have a love and regard for trees of their own planting, so will not be tempted to destroy them themselves, or suffer others to do it; and as the season for planting happens at a time of year when the farmers have little employment for their labourers, so the finding them useful employment this way, will be of infinitely more advantage than the giving them alms from the parish; and the children may be taught to weed and keep the young plants clean in summer, whereby they may be rendered useful, and kept from being burdensome to the parishes.

From the Larch-tree is extracted the Venice turpentine, which the inhabitants of the valley of St. Martin near Lucern, make a considerable merchandize of. They collect this by boring holes in the trunk of the trees, at about two or three feet from the ground, into which they fix narrow troughs about twenty inches long; the end of these are hollowed like a ladle, and in the middle is a small hole bored for the turpentine to run into a receiver, which is placed below it; as the turpentine runs from the trees, it passes along the sloping gutter or trough to the ladle, and from thence runs through the holes into the receiver. The people who gather this visit the trees morning and evening, from the end of May to September, to collect the turpentine from out of the receivers.

The third sort is the Cedar of Libanus, which is a tree of great antiquity; and what is remarkable, this tree is not found as a native in any other part of the world, so far as hath come to our knowledge.

The cones of this tree are frequently brought from the Levant, which, if preserved entire, will preserve their seeds good for several years. The time of their ripening is commonly in the spring, and so consequently are near one year old before we receive them, for which they are not the worse, but rather the better; the cones having discharged a great part of their resin by lying, and the seeds are much easier to get out of them than such as are fresh taken from the tree.

The best way to get the seeds out is to split the cones, by driving a sharp piece of iron through the center lengthways, which will split the cone; then you may pull the seeds out with your fingers, which you will find are fastened to a thin leafy substance called wings, as are those of the Fir-tree: but before the seeds are taken out, it will be proper to put the cones in water for twenty-four or thirty hours, which will render them easier to split, so that the seeds may be taken out with greater safety; for there will require care in the doing of it, otherwise many of the seeds will be spoiled, as they are very tender, and will bruise where there is any force employed to get them out.

These seeds should be sown in boxes or pots of light fresh earth, and treated as was directed for the Firs (to which I refer the reader) but only shall observe, that these require more shade in summer while young than the Firs, and should be frequently refreshed with water.

When the plants come up they must be guarded from the birds, otherwise they will pick off their tops, as they do of the young Firs where they are not guarded; they must also be constantly kept clean from weeds, and not placed under the drip of trees. The plants may remain in these boxes or pots in which they were sown till the following spring, but it will be proper to place them under a frame in winter, or cover them with mats; for while they are young they are in danger of losing their tops, if they are pinched by frost, for the young plants often shoot late in the autumn. In the spring, before the plants begin to shoot, they should be carefully taken up and transplanted into beds at about four inches distance, closing the earth

L A R

gently to their roots; these beds should be arched over with hoops, and covered with mats in the heat of the day, to shade the plants from the sun till they have taken new root; and if the nights prove frosty, it will be proper to keep the mats over them in the night, but in cloudy or moist weather they must be always open. After the plants are well rooted, they will require no other care but to keep them clean from weeds, unless the season should prove very dry, in which case it will be proper to give them some water once or twice a week; but it must be but in small quantities, for too much wet is often very injurious to them; so that it will be better to screen them from the sun in hot weather, to prevent the earth from drying too fast, or cover the surface of the ground with moss to keep it cool, than to water the plants often.

In these beds the plants may stand two years, then they should be either transplanted to the places where they are designed to remain, or to a nursery where they may grow two years more; but the younger these plants are when they are planted out for good, the better the trees will thrive, and the longer they will continue.

When these plants begin to shoot strong, you will generally find the leading shoot incline to one side; therefore, if you intend to have them strait, you must support them with stakes, observing to keep the leader always close tied up, until you have got them to the height you design them, otherwise their branches will extend on every side, and prevent their growing tall.

These trees are by many people kept in pyramids, and sheared as Yews, &c. in which form they lose their greatest beauty; for the extension of the branches is very singular in this tree, their shoots for the most part are declining, and thereby shewing their upper surface, which is constantly clothed with green leaves in so regular a manner, as to appear at some distance like a green carpet; and these waving about with the wind, make one of the most agreeable prospects that can be to terminate a vista, especially if planted on a rising ground.

It is matter of surprise to me, that this tree hath not been more cultivated in England formerly, for till within a few years past, there were but few here; since it would be a great ornament to barren bleak mountains, where few other trees will grow so well, it being a native of the coldest parts of Mount Libanus, where the snow continues great part of the year. And from the observations I have made of those now growing in England, I find they thrive best on the poorest soil; for such of them as have been planted in a strong, rich, loamy earth, have made but a poor progress, in comparison to such as have grown upon a stony meagre soil. And that these trees are of quick growth, is evident from four of them now growing in the physic garden at Chelsea, which (as I have been credibly informed) were planted there in the year 1683, and at that time were not above three feet high; two of which trees are at this time (viz. 1766) upwards of twelve feet and a half in girth, at two feet above ground, and their branches extend more than twenty feet on every side their trunks; which branches (though they are produced twelve or fourteen feet above the surface) do at every termination hang very near the ground, and thereby afford a goodly shade in the hottest season of the year.

The soil in which these trees are planted, is a lean hungry sand mixed with gravel, the surface of which is scarcely two feet deep before a hard rocky gravel appears. These trees stand at four corners of a pond, which is bricked up within two feet of their trunks, so that their roots have no room to spread on one side, and consequently are cramped in their growth; but whether their standing so near the water may not have been advantageous to them, I cannot say, but sure I am, if their roots had had full scope in the ground, they would have made a greater progress. I have also observed, that lopping or cutting of these trees is very injurious to them (more, perhaps, than to any other of the resinous trees) in retarding their growth;

L A R

for two of the four trees above-mentioned, being unadvisedly planted near a green-house, when they began to grow large had their branches lopped, to let the rays of the sun into the house, whereby they have been so much checked, as at present they are little more than half the size of the other two.

These trees have all of them produced, for several years, large quantities of katkins (or male flowers,) though there are but three of them which have as yet produced cones; nor is it above thirty-five years that these have ripened their cones; so as to perfect the seed; but now the seeds which fall out of the cones on the ground near them, produce plants in plenty, which come up naturally without care: and since we find that they are so far naturalized to our country as to produce ripe seeds, we need not fear being soon supplied with enough, without depending on those cones which are brought from the Levant; as there are many trees of this kind in England, which already do, and abundance more which in a few years must certainly bear: but I find they are more subject to produce and ripen their cones in hard winters than in mild ones; which is a plain indication, that they will succeed, even in the coldest parts of Scotland, where, as well as in England, they might be propagated to great advantage.

What we find mentioned in scripture of the lofty Cedars, can be no ways applicable to the stature of this tree; since, from the experience we have of those now growing in England, as also from the testimony of several travellers, who have visited those few remaining trees on Mount Libanus, they are not inclined to grow very lofty, but, on the contrary, extend their branches very far; to which the allusion made by the Psalmist agrees very well, when he is describing the flourishing state of a people, and says, They shall spread their branches like the Cedar-tree.

Rauwolf, in his Travels, says, there were not at that time (i. e. anno 1574) upon Mount Libanus more than 26 trees remaining, 24 of which stood in a circle; and the other two, which stood at a small distance, had their branches almost consumed with age; nor could he find any younger trees coming up to succeed them, though he looked about diligently for some. These trees (he says) were growing at the foot of a small hill, on the top of the mountains, and amongst the snow. These having very large branches, commonly bend the tree to one side, but are extended to a great length, and in so delicate and pleasant order, as if they were trimmed and made even with great diligence, by which they are easily distinguished at a great distance from Fir-trees. The leaves (continues he) are very like to those of the Larch-tree, growing close together in little bunches upon small brown shoots.

Maundrel in his Travels, says, there were but sixteen large trees remaining when he visited the mountains, some of which were of a prodigious bulk, but that there were many more young trees of a smaller size; he measured one of the largest, and found it to be 12 yards 6 inches in girth, and yet sound, and 37 yards in the spread of its boughs. At about five or six yards from the ground it was divided into five limbs, each of which was equal to a great tree. What Maundrel hath related, was confirmed to me by a worthy gentleman of my acquaintance, who was there in the year 1720, with this difference only, viz. in the dimensions of the branches of the largest tree, which he assured me he measured, and found to be twenty-two yards diameter. Now, whether Mr. Maundrel meant thirty-seven yards in circumference of the spreading branches, or the diameter of them, cannot be determined by his expressions, yet either of them well agrees with my friend's account.

Monsieur Le Brun reckons about 35 or 36 trees remaining upon Mount Libanus when he was there, and would persuade us it was not easy to reckon their numbers (as is reported of our Stonehenge on Salisbury Plain.) He also says, their cones do some of them grow dependent. Which is abundantly confuted by the above-mentioned travellers, as also from our own experience,

experience, for all the cones grow upon the upper part of the branches, and stand erect, having a strong, woody, central style, by which it is firmly annexed to the branch, so as with difficulty to be taken off; which central style remains upon the branches after the cone is fallen to pieces, so that they never drop off whole, as the Pines do.

The wood of this famous tree is accounted proof against all putrefaction of animal bodies; the sawdust of it is thought to be one of the secrets used by those mountebanks, who pretend to have the embalming mystery. This wood is also said to yield an oil, which is famous for preserving books and writings; and the wood is thought by my Lord Bacon, to continue above a thousand years sound. It is also recorded, that in the temple of Apollo at Utica, there was found timber of near two thousand years old. And the statue of the goddess, in the famous Ephesian temple, was said to be of this material also, as was most of the timber work of that glorious structure.

This sort of timber is very dry and subject to split, nor does it well endure to be fastened with nails, from which it usually shrinks, therefore pins of the same wood are much preferable.

LARKSPUR. See DELPHINIUM.

LASERPITIUM. Tourn. Inst. R. H. 324. tab. 172. Lin. Gen. Plant. 306. Laserwort.

The CHARACTERS are,

It hath an umbellated flower, composed of many small umbels; both the small and principal umbels have a many-leaved involucre. The general umbel is uniform; the flowers have five equal petals, whose points are heart-shaped and inflexed; they have five stamina which are as long as the petals, terminated by single summits; the roundish germen is situated under the flower, supporting two thick acuminate styles, crowned by obtuse spreading stigmas. The germen afterward becomes an oblong fruit with eight longitudinal wings or membranes, resembling the slier of a water-mill; the fruit divides into two parts, each containing one seed.

This genus of plants is ranged by Dr. Linnæus's in the second section of his fifth class, intitled Pentandria Digynia, which includes those plants whose flowers have five stamina and two styles.

The SPECIES are,

1. LASERPITIUM (Commune) foliolis oblongo-cordatis, inciso-ferratis. *Laserwort with oblong heart-shaped lobes, which are cut like a saw. Laserpitium foliis latioribus lobatis.* Mor. Umbel. 29. *Laserwort with broader leaves, having lobes.*
2. LASERPITIUM (Latifolium) foliolis-cordatis inciso-ferratis. Hort. Cliff. 96. *Laserwort with heart-shaped lobes cut like a saw. Laserpitium foliis amplioribus, semine crispo.* Inst. R. H. 324. *Laserwort with large leaves and curled seeds.*
3. LASERPITIUM (Paludapifolium) foliolis ovatis obtusis acutè ferratis. *Laserwort with oval obtuse lobes sharply sawed. Laserpitium humilius, paludapii folio, flore albo.* Inst. R. H. *Lower Laserwort, with a Smallage leaf and a white flower.*
4. LASERPITIUM (Gallicum) foliolis cuneiformibus furcatis. Lin. Sp. Plant. 248. *Laserwort with wedge-shaped forked lobes. Laserpitium Gallicum.* 156. C. B. P. *French Laserwort.*
5. LASERPITIUM (Angustifolium) foliolis lanceolatis integerrimis sessilibus. Hort. Cliff. 96. *Laserwort with spear-shaped entire leaves sitting close to the branches. Laserpitium angustissimo & oblongo folio.* Inst. R. H. 324. *Laserwort with a very narrow oblong leaf.*
6. LASERPITIUM (Selinoides) foliolis trifidis acutis. *Laserwort with acute trifid lobes. Laserpitium selinoides, semine crispo.* Inst. R. H. *Laserwort resembling sweet Smallage, with a curled seed.*
7. LASERPITIUM (Trilobum) foliolis trilobis incis. Lin. Sp. 357. *Laserwort with trifid leaves. Libanotis latifolia aquilegiæ folio.* C. B. P. 157.
8. LASERPITIUM (Prutenicum) foliolis lanceolatis integerrimis extimis coalitis. *Laserwort with spear-shaped entire lobes, whose outer ones coalesce. Laserpitium*

daucoides prutenicum viscoso semine. Breyh. Cent. 167.

9. LASERPITIUM (Pseudanoides) foliolis lineari-lanceolatis venoso-striatis distinctis Amœnit. Acad. 4. p. 310. *Laserwort with linear spear-shaped leaves, which are distinct and veined. Laserpitium exoticum, lobis angustissimis integris.* Pluk. Phyt. tab. 96. f. 2.
10. LASERPITIUM (Siler) foliolis ovato-lanceolatis integerrimis petiolatis. Hort. Cliff. 96. *Laserwort with oval, spear-shaped, entire leaves, having foot-stalks. Siler Montanum.* Mor. Hist. 3. p. 276.
11. LASERPITIUM (Chironium) foliolis oblique cordatis, petiolis hirsutis. Lin. Sp. 358. *Laserwort with oblique heart-shaped lobes, having hairy foot-stalks. Panax Heracleum.* Mor. Hist. 3. p. 315. *Herculus's All-heal.*
12. LASERPITIUM (Ferulaceum) foliolis linearibus. Lin. Sp. 358. *Laserwort with linear leaves. Cachrys Orientalis, ferulæ folio tenuiore, fructu alato plano.* Tourn. Cor. 23.

There are some other varieties, if not distinct species of this plant; some of which have been put down as distinct species, which differ only in the colour of their flowers, therefore should not be regarded as such; but the number of species has been greatly lessened by some late writers, who have erred as much in lessening, as those before them had done in multiplying of the species: which mistake they may have fallen into by sowing of the seeds near old plants of the same genus, or on ground where some of these sorts have grown, so that their seeds have been scattered and buried in the ground, where they will remain two or three years, and afterward grow; so that unless their seeds are sown at a distance from any of the other species, there will commonly some other species come up, whereby people have been often confused in distinguishing these plants; nay, I have frequently observed the seeds of one species fall, and the plants come up on the head of another plant which grew near it; and this young plant, if not timely rooted out, has gotten the better of the old plant, and destroyed it; therefore where there is not great care taken to prevent this, the different sorts cannot be preserved in gardens where the species grow near each other.

These plants grow naturally in the south of France, in Italy, and Germany, and are preserved in botanic gardens for the sake of variety; but as they have no great beauty, so are seldom cultivated in other gardens: they require much room, for their roots extend far every way, and the leaves of many sorts will spread three feet, when the plants are strong; their flower-stalks rise four or five feet high, and their umbels of flowers are very large; they have all of them perennial roots but annual stalks. They flower in June, and the seeds ripen in September.

It is generally supposed, that the Silphium of the ancients was procured from one species of this genus, but from which of them we are at present ignorant. All the species, if wounded, drop a very acrid juice, which turns to a resinous gummy substance, very acrimonious. This was externally applied by the ancients to take away black and blue spots that came by bruises and blows, as also to take away excrescences; it was also by some of the ancients prescribed in internal medicines, but others have cautioned people not to make use of it this way, from the effects which they mention to have been produced from the violence of its acrimony.

All these plants are extreme hardy, except the last, which requires a warmer situation, otherwise will be killed in sharp winters; the other sorts will thrive in most soils and situations; they are propagated by seed, which if sown in autumn, the plants will come up the following spring; but when they are sown in the spring, the seeds commonly remain in the ground a whole year. The plants should be transplanted the following autumn where they are designed to remain, for they send out long deep roots, which are frequently broken by transplanting if they are large; when the plants are removed, they should be planted three

three feet asunder, for they grow very large; they decay to the ground every autumn, and come up again the following spring, but the roots will continue many years, and require no other culture but to clear them from weeds, and to dig between the roots every spring.

LATHYRUS. Tourn. Inst. R. H. 394. tab. 216, 217. Lin. Gen. Plant. 781. Chickling Vetch; in French, Gesse.

The CHARACTERS are,

The flower has a bell-shaped empalement of one leaf, cut into five parts at the top, the two upper being short, and the under longer. The flower is of the butterfly kind. The standard is heart-shaped, large, and reflexed at the point. The wings are oblong and blunt; the keel is half round, the size of the wings. It hath ten stamina, nine of them joined, and one separate, crowned by roundish summits. It hath an oblong, narrow, compressed germen, supporting a rising style, which is flat, and the upper part broad, with an acute point, crowned by a hairy stigma. The germen afterward becomes a long compressed pod, ending in a point, having two valves, and filled with roundish seeds.

This genus of plants is ranged in the third section of Linnæus's seventeenth class, intitled Diadelphia Decandria which includes those plants whose flowers have ten stamina formed in two bodies.

The SPECIES are,

1. **LATHYRUS (Sativus)** pedunculis unifloris, cirrhis diphyllis, leguminibus ovatis compressis dorso bimar-ginatis. Hort. Cliff. 367. Chickling Vetch with one flower upon a foot-stalk, tendrils having two leaves, and oval compressed pods with two borders on their back part. Lathyrus annuus, flore cæruleo, Ochri siliquâ. H. L. Annual Chickling Vetch with a blue flower, and a pod like Ochrus.
2. **LATHYRUS (Cicera)** pedunculis unifloris, cirrhis diphyllis, leguminibus ovatis compressis, dorso canali-culatis. Lin. Sp. Plant. 730. Chickling Vetch with one flower upon a foot-stalk, two-leaved tendrils, and an oval compressed pod a little channelled on the back. Lathyrus sativus flore purpureo. C. B. P. 344. Cultivated Chickling Vetch with a purple flower.
3. **LATHYRUS (Setifolius)** pedunculis unifloris, cirrhis diphyllis, foliolis setaceo-linearibus. Lin. Sp. 1031. Chickling Vetch with one flower upon a foot-stalk, a two-leaved tendril, and linear bristly lobes. Lathyrus foliis angustis, floribus singularibus coccineis. Seg. Pl. Veron. Chickling Vetch, with narrow leaves and single scarlet flowers.
4. **LATHYRUS (Parisensis)** pedunculis unifloris, cirrhis polyphyllis, stipulis lanceolatis. Hort. Cliff. 368. Chickling Vetch with one flower upon a foot-stalk, a many-leaved tendril, and spear-shaped stipulæ. Clyme-num Parisiense flore cæruleo. Tourn. Inst. R. H. 396. Chickling Vetch of Paris with a blue flower.
5. **LATHYRUS (Hispanicus)** pedunculis bifloris, cirrhis polyphyllis, foliolis alternis. Hort. Cliff. Chickling Vetch with two flowers upon a foot-stalk, a many-leaved tendril, and the lobes placed alternate. Clyme-num Hispanicum, flore vario siliquâ articulata. Tourn. Inst. R. H. 296. Spanish Chickling Vetch, with a variable flower and jointed pod.
6. **LATHYRUS (Odoratus)** pedunculis bifloris, cirrhis diphyllis, foliis ovato-oblongis, leguminibus hirsutis. Hort. Cliff. 368. Chickling Vetch with two flowers on a foot-stalk, a two-leaved tendril, oblong oval leaves, and hairy pods. Lathyrus distoplatyphyllos hirsutus, mollis, magno & peramæno flore odore. Hort. Cath. The sweet-scented Pea.
7. **LATHYRUS (Hirsuta)** pedunculis bifloris, cirrhis diphyllis, foliolis lineari-lanceolatis, leguminibus hirsutis, seminibus scabris. Flor. Leyd. Prod. 363. Chickling Vetch with two flowers on a foot-stalk, a two-leaved tendril, narrow spear-shaped lobes, hairy pods, and rough seeds. Lathyrus angustifolius siliquâ hirsutâ. C. B. P. Narrow-leaved Chickling Vetch with a hairy pod.
8. **LATHYRUS (Tingitanus)** pedunculis bifloris, cirrhis diphyllis foliolis alternis lanceolatis. Flor. Leyd.

Prod. 263. Chickling Vetch with two flowers on a foot-stalk, a two-leaved tendril, and spear-shaped alter-nate leaves. Lathyrus Tingitanus filiquis orobi flore amplo ruberrimo. Mor. Hist. 2. 55. Chickling Vetch of Tangier, with a bitter Vetch pod, and a large red flower.

9. **LATHYRUS (Annuus)** pedunculis bifloris, cirrhis diphyllis, foliolis ensiformibus, leguminibus glabris, stipulis bipartitis. Amœn. Acad. 3. p. 417. Chickling Vetch with two flowers on a foot-stalk, a two-leaved tendril, sword-shaped lobes, smooth pods, and a bifid stipula. Lathyrus luteus latifolius. Bot. Monsp. Yellow broad-leaved Chickling Vetch.
 10. **LATHYRUS (Tuberosus)** pedunculis multifloris, cirrhis diphyllis, foliolis ovalibus, internodis nudis. Hort. Cliff. 367. Chickling Vetch with many flowers on a foot-stalk, a two-leaved tendril, oval leaves, and naked be-tween the joints. Lathyrus arvensis repens tuberosus. C. B. P. 344. Creeping Field Chickling Vetch with a tuberous root.
 11. **LATHYRUS (Pratensis)** pedunculis multifloris, cirrhis diphyllis, foliolis lanceolatis cirrhis simplicissi-mis. Hort. Cliff. 367. Chickling Vetch with many flowers on a foot-stalk, a two-leaved tendril, spear-shaped leaves, and single tendrils. Lathyrus luteus syl-vestris dumetorum. J. B. 2. p. 304. Yellow wild Chickling Vetch of the woods.
 12. **LATHYRUS (Heterophyllus)** pedunculis multifloris, cirrhis diphyllis tetraphyllisque, foliolis lanceolatis. It. W. Goth. 75. Chickling Vetch with many flowers on a foot-stalk, a two-leaved, and sometimes four-leaved ten-dril, and spear-shaped leaves. Lathyrus major Narbo-nensis angustifolius. J. B. 2. 304. Greater Chickling Vetch of Narbonne with narrow leaves.
 13. **LATHYRUS (Latifolius)** pedunculis multifloris, cirrhis diphyllis, foliolis lanceolatis, internodiis membra-naceis. Hort. Cliff. 367. Chickling Vetch with many flowers on a foot-stalk, a two-leaved tendril, spear-shaped leaves, and a membranaceous stalk between the joints. Lathyrus latifolius. C. B. P. 344. Broad-leaved Chickling Vetch, commonly called Everlasting Pea.
 14. **LATHYRUS (Magniflora)** pedunculis multifloris, cirrhis diphyllis foliolis ovato-lanceolatis, internodiis membranaceis. Chickling Vetch with many flowers on a foot-stalk, a two-leaved tendril, oval spear-shaped leaves, and a membranaceous stalk between the joints. Lathy-rus latifolius minor flore majore. Boerh. Ind. alt. 2. p. 42. Smaller broad-leaved Chickling Vetch with a larger flower, or large, red, flowering, Everlasting Pea.
 15. **LATHYRUS (Pisiformis)** pedunculis multifloris, cirrhis polyphyllis, stipulis ovatis, basi acutis. Hort. Upsal. 217. Chickling Vetch with many flowers on a foot-stalk, a many-leaved tendril, and oval stipulæ acute at the base.
 16. **LATHYRUS (Nissolia)** pedunculis unifloris, foliis simplicibus stipulis subulatis. Lin. Sp. Plant. 729. Chickling Vetch with one flower on a foot-stalk, single leaves, and awl-shaped stipulæ. Nissolia vulgaris. Tourn. Inst. 656. Crimson Grass Vetch.
 17. **LATHYRUS (Amphicarpos)** pedunculis unifloris calyce longioribus, cirrhis diphyllis simplicissimis subtus ve-nosis. Chickling Vetch with single flowers upon a foot-stalk, which are longer than the empalement, and a two-leaved single tendril.
 18. **LATHYRUS (Aphaca)** pedunculis unifloris, cirrhis aphyllis, stipulis sagitto-cordatis. Lin. Sp. 1029. Chickling Vetch with one flower on each foot-stalk, a ten-dril without leaves, and a heart arrow-shaped stipula. Aphacha. Lob. Ic. 2. p. 70.
 19. **LATHYRUS (Americana)** pedunculis bifloris, foliis reniformibus simplicissimis subtus venosis. Chickling Vetch with two flowers upon a foot-stalk, and kidney-shaped single leaves, which are veined on their under side. Nissolia Americana procumbens, folio rotundo, flore luteo. Houst. MSS. Trailing American Nissolia, with a round leaf and a yellow flower.
- The first sort grows naturally in France, Spain, and Italy; this is an annual plant, with a climbing stalk about two feet high. The leaves come out at each joint alternate; they are composed of two long narrow lobes,

L A T

lobes, with a tendril or clasper rising between, which fastens to any support near. The flowers come singly upon foot-stalks at each joint; they are blue, and shaped like those of the Pea; these are succeeded by oval compressed pods, with a double membrane or wing running longitudinally on the back. This flowers in June and July, and the seeds ripen in September. It is seldom cultivated, unless in botanic gardens for the sake of variety.

The second sort is cultivated in some countries for the seeds, which are used for feeding of poultry; this grows wild in Italy and Spain. It does not rise so high as the first sort. The leaves are longer, the pods are near twice the length of those, and are channelled on their back side; this is cultivated in the same manner as Vetches or Tares.

The third sort was sent me from Verona, where it grows naturally; this is an annual plant, which seldom rises more than six or eight inches high. The two lobes of the leaves are small, and end with clasps. The flowers are of a bright scarlet, and are succeeded by taper pods, filled with roundish seeds. This is only kept for variety in some botanic gardens.

The fourth sort grows naturally about Paris; this is an annual plant, with a slender stalk about one foot high, garnished with leaves, composed of several narrow lobes placed alternate along the midrib, which end in clasps. The flowers come out singly upon pretty long foot-stalks; they are blue, and about the size of those of the common Tare. It grows naturally in some parts of England, particularly on Windsor forest, in moist meadows, and has often a variable flower.

The fifth sort grows naturally in Spain and Italy; it is an annual plant, with a climbing stalk which rises near three feet high, garnished with leaves composed of several lobes, which are spear-shaped, placed alternately along the midrib, which is terminated by very long clasps. The foot-stalks of the flowers are five or six inches long, upon which stand two flowers one above the other, shaped like those of the Pea. The standard, which is large, is of a bright red colour, but the keel and wings are white. The flowers are succeeded by pretty long jointed pods, filled with roundish seeds. This flowers in June and July, and the seeds ripen in autumn.

The sixth sort is commonly known by the title of Sweet Pea; this grows naturally in Ceylon, but is hardy enough to thrive in the open air in England. It is an annual plant with a climbing stalk, which rises from three to four feet high, garnished with leaves composed of two large oval lobes, whose midrib is terminated by long clasps. The foot-stalks come out at the joints; they are about six inches long, and sustain two large flowers with dark purple standards; the keel and wings are of a light blue colour. The flowers have a strong sweet odour, and are succeeded by oblong inflated pods, which are hairy, containing four or five roundish seeds in each.

There are two other varieties of this sort, one of which has a Pink-coloured standard with a white keel, and the wings of a pale blush colour; this is commonly called Painted Lady Pea. The flowers of the other are all white, which are the only differences between them.

The seventh sort grows naturally in Essex. I have found it in places which were spread over with Brambles, near Hockerel; this hath a perennial root, sending out three or four weak stalks, which are near two feet long, garnished with leaves composed of two oblong lobes, whose midrib is terminated by clasps. The foot-stalks are about four inches long, and sustain two purple flowers, which are succeeded by rough hairy pods, little more than an inch long, containing three or four roundish seeds. This sort is very rarely preserved in gardens.

The eighth sort was originally brought from Tangier to England; this is an annual plant, whose stalk rises four or five feet high, garnished with leaves composed of two oval veined lobes, whose midrib ends

L A T

with clasps. The foot-stalks are short, and sustain two large flowers with purple standards, whose wings and keel are of a bright red; these are succeeded by long jointed pods, containing several roundish seeds. This is sometimes titled by the gardeners Scarlet Lupine.

The ninth sort is an annual plant, which grows naturally about Montpellier. I have also received the seeds from Siberia; this rises with a climbing stalk five or six feet high, which has two membranes, or wings, running along from joint to joint. The leaves are composed of two long narrow lobes, whose midrib ends with clasps. The flowers stand upon long foot-stalks, each sustaining two pale yellow flowers, which are succeeded by long taper pods, containing several roundish seeds.

The tenth sort grows naturally amongst the Corn in the South of France, and in Italy, but is cultivated in the Dutch gardens for the roots, which are there sold in the markets, and are commonly eaten: this hath an irregular tuberous root about as big as those of the Pignut, covered with a brown skin; these shoot up several weak trailing stalks, garnished with leaves composed of two oval lobes, ending with clasps. The foot-stalks of the flowers are weak, about three inches long, each sustaining two deep red flowers, which are seldom succeeded by pods, but the roots increase plentifully in the ground. This sort will grow in moist soils, but will thrive best on light ground.

The eleventh sort grows naturally on the banks and under thickets in moist parts of England; this hath a perennial creeping root, whereby it propagates so fast as to be a very troublesome weed, so should not be admitted into gardens.

The twelfth sort grows naturally by the side of hedges, and in thickets, in several parts of England; this hath a perennial creeping root, which sends out many climbing stalks which rise five or six feet high, garnished with leaves, which have sometimes two, and at others four long narrow lobes, terminated by clasps. The foot-stalks sustain several small flowers with pale standards, whose wings and keels are blue; these are succeeded by long taper pods, containing several roundish seeds. It flowers in June and July, and the seeds ripen in autumn.

The thirteenth sort has been found growing naturally in several parts of England, but is frequently cultivated in gardens for ornament, therefore it is doubtful if it is a native here; this hath a perennial root, from which arise several thick climbing stalks from six to eight feet high, which have membranaceous wings on each side between the joints. The leaves are composed of two spear-shaped lobes, and the midrib is terminated by clasps. The foot-stalks are eight or nine inches long, and sustain several large red flowers, which are succeeded by long taper pods, containing several roundish seeds. It flowers in June, July, and August, and the seeds ripen in autumn, soon after which the stalks die to the root, and new ones arise in the spring, from whence it is called Everlasting Pea.

The fourteenth sort differs from the last in the stalks, being much shorter and stronger. The leaves are broader, and of a deeper green. The flowers are much larger, and of a brighter red colour, so make a better appearance; these differences are lasting from seeds, for I have raised many plants from seeds within forty years past, and have always found them to be the same as the parent plant.

The fifteenth sort grows naturally in Siberia; this hath a perennial root and an annual stalk, which is garnished with leaves, composed of six or eight pair of oblong acute lobes. The flowers are blue, and many of them stand upon each foot-stalk; these are succeeded by pods, shaped like those of the Pea. It flowers in June, and the seeds ripen in August.

The sixteenth sort grows naturally in moist meadows in many parts of England; this rises with an upright stalk one foot high, which is garnished with

long, narrow, single leaves at each joint. The foot-stalks of the flowers come out from the joints toward the upper part of the stalk; they are slender, about three inches long, some having but one, and others have two bright red flowers on their tops. It flowers in May and June, and the seeds ripen in autumn. This is rarely kept in gardens.

The seventeenth sort grows naturally in Syria; this is an annual plant with a trailing stalk, garnished with leaves composed of two lobes, whose midrib is terminated by a single tendril. The foot-stalk supports one flower of a pale purple colour, and when the flowers decay, the germen is thrust into the ground, where the pods are formed, and the seeds ripen.

The eighteenth sort was discovered by the late Dr. Houlstoun, growing naturally at La Vera Cruz in New Spain; this is annual plant, with a trailing stalk a foot long, garnished with a single kidney-shaped leaf at each joint. The flowers grow two together upon very short foot-stalks; they are small, and of a deep yellow colour; these are succeeded by short taper pods, including three or four small roundish seeds.

This sort is tender, so the seeds should be sown upon a hot-bed in the spring, and when the plants are fit to remove, they should be each planted into a small pot filled with light earth, and plunged into a tan-bed, where they should constantly remain, treating them in the same manner as other tender plants from warm countries; if they are brought forward in the spring, they will flower in July, and their seeds will ripen in autumn.

Several of the other sorts are preserved in curious gardens for the variety of their flowers, some of which make a fine appearance, and continue long in flower. These may all be propagated by sowing their seeds, either in spring or autumn; but those which are sowed in autumn should have a light soil and a warm situation, where the plants will abide the winter, and come to flower early the following spring, and their seeds will ripen in July; but those which are sown in the spring should have an open exposure, and be planted upon almost any soil, if not too wet, for they are not tender plants, nor do they require much culture: these sorts should all of them be sown where they are designed to remain, for they seldom succeed when they are transplanted, unless it is done while the plants are young; so that where they are sown for ornament, there should be four or five seeds sown in a small patch, in different parts of the borders of the flower-garden; and when the plants come up, they should be carefully kept clear from weeds; but when they are grown two or three inches high, there should be some sticks put down by them to support them, otherwise they will trail on the ground, or on whatever plants stand near them, and become unsightly.

The sixth sort, with the two varieties of it, are deserving room in every good garden for the beauty and odour of their flowers; and the eighth sort is by some cultivated for the colour of the flowers; but there are few of the other sorts worthy of room in gardens, except the thirteenth and fourteenth sorts, which, if they are planted in a proper situation, and are rightly trained, will make a fine appearance.

LATIFOLIUS trees and plants are such as have broad leaves.

LAVATERA. Tourn. Act. Gal. 1706. tab. 3. Dill. Gen. 10. Lin. Gen. Plant. 752.

The CHARACTERS are,

The flower has a double empalement; the outer is of one leaf, short, obtuse, and trifid; the inner is of one leaf, and quinquefid; they are both permanent. The flower hath five petals, which are joined at their base, plain, and spread open above. It has many stamina, which are joined in a column below, but above are loose; they are inserted in the petal, and terminated by kidney-shaped summits. It has an orbicular germen, supporting a short cylindrical style, crowned by many bristly stigmas. The empalement afterward becomes a fruit with several capsules, covered

in front by a hollow shield, each capsule having one kidney-shaped seed.

This genus of plants is by Dr. Linnæus ranged in the fifth order of his sixteenth class, intitled Monodelphia Polyandria, which includes those plants whose flowers have many stamina joined in a column.

The SPECIES are,

1. **LAVATERA** (*Althæaefolia*) foliis infimis cordato-orbiculatis, caulinis trilobis acuminatis glabris, pedunculis unifloris, caule herbaceo. *Lavatera whose lower leaves are orbicularly heart-shaped, those on the stalks set with three acute smooth lobes, and one flower upon a foot-stalk, and an herbaceous stalk.* Lavatera folio & facie althææ. Act. R. P. 1706. *Lavatera with the leaves and appearance of Marshmallow.*
2. **LAVATERA** (*Africana*) foliis infimis cordato-angulatis, supernè sagittatis, pedunculis unifloris, caule herbaceo hirsuto. *Lavatera with the lower leaves angularly heart-shaped, the upper ones arrow-pointed, a single flower upon each foot-stalk, and a hairy herbaceous stalk.* Lavatera Africana, flore pulcherrimo. Boerh. Ind. alt. *African Lavatera with a beautiful flower.*
3. **LAVATERA** (*Trimestris*) foliis glabris, caule scabro herbaceo, pedunculis unifloris, fructibus orbiculo rectis. Hort. Upsal. 203. *Lavatera with smooth leaves, a rough herbaceous stalk, one flower upon a foot-stalk, and an orbicular closed fruit.* Malva folio vario. C. B. P. *Mallow with a variable leaf.*
4. **LAVATERA** (*Thuringiaca*) caule herbaceo, fructibus denudatis, calycibus incis. Hort. Upsal. 203. *Lavatera with an herbaceous stalk, naked fruit, and a cut empalement.* Althæa flore majore. C. B. P. 316. *Marshmallow with a larger flower.*
5. **LAVATERA** (*Hirsuta*) foliis quinquelobatis hirsutis, caule erecto fruticoso. Icon. tab. 161. *Lavatera with hairy leaves having five lobes, and a shrubby upright stalk.*
6. **LAVATERA** (*Veneta*) caule arboreo, foliis septemangularibus tomentosis plicatis, pedunculis confertis unifloris axillaribus. Hort. Upsal. 202. *Lavatera with a tree-like stalk, woolly plaited leaves having seven angles, and foot-stalks with single flowers arising in clusters from the wings of the leaves.* Malva arborea veneta dicta, parvo flore. C. B. P. 215. *Tree Mallow with a small flower.*
7. **LAVATERA** (*Triloba*) caule fruticoso, foliis subcordatis subtrilobis rotundatis crenatis stipulis cordatis, pedunculis unifloris. Lin. Sp. Plant. 691. *Lavatera with a shrubby stalk, heart-shaped leaves having three round indented lobes, which are crenated, heart-shaped stipule, and foot-stalks with single flowers.* Althæa frutescens, folio rotundiore incano. C. B. P. 316. *Shrubby Marshmallow with a rounder hoary leaf.*

nating the stalks. *Althæa frutescens, folio bryoniæ.* C. B. P. 316. *Shrubby Althæa with a Briony leaf.*

The first sort grows naturally in Syria; it is an annual plant, with an erect, branching, herbaceous stalk, rising two feet high; the under leaves are orbicularly heart-shaped, smooth, and stand upon long foot-stalks, the upper are divided into three acute lobes; the flowers come out upon long foot-stalks from the wings of the leaves; they are very large, and spread open like those of the Marshmallow, and are of a pale red or Rose colour. These come out in July, the seeds ripen in September, and the plants decay in autumn.

There is a variety of this with white flowers, which has accidentally risen from seeds.

The second sort grows naturally at the Cape of Good Hope, from whence the seeds were brought to Holland, and the plants there cultivated, and the seeds have since been communicated to most parts of Europe. This differs from the first in the shape of the leaves, the lower having angles, and the upper being arrow-pointed; the stalks are hairy, the flowers larger, and of a brighter red colour.

This sort is annual, and flowers at the same time with the former, and the seeds are ripe in the autumn.

The third sort grows naturally in Spain and Sicily; this is an annual plant, which rises with slender herbaceous stalks about two feet high, covered with a brown bark; the lower leaves are roundish, and the upper are angular, and some arrow-pointed. The flowers are not half so large as those of either of the former, and are of a pale red colour; these stand upon short foot-stalks, and appear about the same time with the former. This is certainly a distinct species, for I have cultivated it more than forty years, and I have never found it vary.

The fourth sort hath a perennial root and an annual stalk, which rises five or six feet high, is woolly, garnished with angular heart-shaped leaves, standing upon long foot-stalks. The flowers come out from the wings of the leaves toward the top, sitting close to the stalks at every joint; they are of a purplish colour, and shaped like those of the Marshmallow, but are larger. These appear in July and August, and the seeds ripen in the autumn, then the stalks decay to the root. It grows naturally in Austria and Bohemia.

The fifth sort grows naturally at the Cape of Good Hope, the seeds of it were sent me by the ingenious Mr. Storm, gardener at Amsterdam. This rises with a shrubby branching stalk to the height of eight or ten feet, garnished with large hairy leaves, deeply divided into five roundish lobes, which are indented on their edges, of a bright green, standing alternately upon long foot-stalks; as the plants become more shrubby the leaves decrease in size, so that the upper leaves are not more than a sixth part of the bigness of the first or lower leaves. The flowers come out singly at the wings of the leaves at every joint, so that as the branches extend there is a succession of flowers, whereby the plants are seldom destitute of them the whole year. The flowers are of a bright purple colour, but are not very large; these are succeeded by capsules having many partitions, in each of these is one kidney-shaped seed, which ripen in succession as the flowers are produced.

The sixth sort is commonly called Mallow-tree; this rises with a very strong thick stalk the height of eight or ten feet, dividing into many branches at the top, which are garnished with soft woolly leaves that are plaited, and the edges cut into several angles. The flowers are produced in clusters at the wings of the leaves, each standing upon a separate foot-stalk; they are of a purple colour, and shaped like those of the common Mallow, and are succeeded by seeds of the same form. This sort flowers from June to September, and the seeds are ripe in the autumn.

The seventh sort rises with a shrubby stalk seven or eight feet high, sending out several long branches,

garnished with woolly leaves, differing greatly in size and shape, the lower being partly heart-shaped at their base, but divide into five roundish lobes; the upper, which are small, have three lobes, which are indented on their edges. The flowers come out from the wings of the stalk, three or four at each joint, upon very short foot-stalks; they are of a light purple colour, and shaped like those of Marshmallow. There is a succession of these flowers from June to the autumn.

The eighth sort is a shrub which grows to the same size as the seventh, and differs from it in the shape of the leaves, which are divided into three or five acute-pointed lobes; the flowers are smaller, but of the same shape and colour, it continues in flower at the same time. This grows naturally in the south of France.

The ninth sort rises with a shrubby stalk six or eight feet high, sending out many branches, garnished with roundish, crenated, woolly leaves, standing upon long foot-stalks; the foot-stalks of the flowers come out in clusters from the wings of the leaves, each sustaining one large pale blue flower, of the same shape with those of the other species. This flowers at the same time with them, and the seeds ripen in the autumn.

The tenth sort hath a soft, shrubby, woolly stalk, which rises to the height of four or five feet; these stand more erect than either of the former sorts, and do not branch so much; the leaves are heart-shaped at their base, but round on their edges, very hoary and waved, standing upon long foot-stalks. The flowers come out in clusters from the wings of the leaves, standing upon foot-stalks of different lengths; these generally support but one flower, but sometimes they have two or three; the flowers are large, and of a pale blue colour. They appear at the same time with the former, and their seeds ripen in the autumn. It grows naturally in Portugal.

The eleventh sort rises with a shrubby stalk six or seven feet high, sending out several shrubby branches, which are garnished with woolly leaves, divided into five lobes, which end in acute points, and are crenated on their edges; the lower part of the branches are adorned with a single flower at each joint, sitting close to the stalk, but the branches are terminated by loose spikes of flowers, which are of a pale blue colour, and shaped like those of the former.

The six last mentioned sorts, though they have shrubby stalks, yet are but of short duration here; the sixth, tenth, and eleventh sorts, seldom continue longer than two years, unless when they happen to grow upon dry rubbish, where they make but little progress, and their stalks and branches being firmer, so are better able to resist the cold; for when they are in good ground, they are very vigorous and full of sap, so are killed by the frost in common winters. The other three sorts are not quite so tender, nor of so short duration; these will continue three or four years, and sometimes longer, provided the winters are not very severe; or if the plants stand in a warm situation and on a dry soil, but in moist rich ground they seldom continue long.

All these shrubby sorts are easily propagated by seeds, which should be sown in the spring upon a bed of light earth; and when the plants are about three or four inches high, they should be transplanted to the places where they are designed to remain; for as they shoot out long fleshy roots which have but few fibres, so they do not succeed well if they are transplanted after they are grown large. If the seeds of these plants are permitted to scatter on the ground, the plants will come up the following spring; and when they happen to fall into dry rubbish, and are permitted to grow therein, they will be short, strong, woody, and produce a greater number of flowers than those plants which are more luxuriant. As these plants continue a long time in flower, so a few plants of each sort may be allowed a place in all gardens where there is room.

The

The three first sorts are annual plants, which are propagated by seeds: the season for sowing them is the end of March or the beginning of April, upon a bed of fresh light earth; and when the plants are come up, you must carefully clear them from weeds; and in very dry weather they must be now and then refreshed with water. When they are about two inches high, you must transplant them into the places where they are designed to remain, which should be in the middle of the borders in the flower-garden; for if the soil is good, they will grow two or three feet high; in transplanting them, you must take them up very carefully, preserving a ball of earth to their roots, otherwise they are apt to miscarry; and also water and shade them until they have taken root, after which they will require no other care but to clear them from weeds, and to fasten them to stakes, to prevent their being injured by strong winds. You may also sow their seeds in autumn, and when the plants are come up, transplant them into small pots, which, towards the end of October, should be placed in a common hot-bed frame, where the plants being defended from severe frosts, will abide the winter very well; and in the spring, you may shake them out of the pots, and plant them into larger, or else into the full ground, where they may remain to flower. The plants thus managed will be larger, and flower stronger and earlier than those sown in the spring, and from these you will constantly have good seeds, whereas those sown in the spring sometimes miscarry. The seeds of the third sort should be sown in the spring in the place where they are to remain, for they do not well bear removing in the summer.

The two first sorts are very ornamental plants in a fine garden, when placed among other annuals, either in pots or borders.

The fourth sort hath a perennial root which abides several years, but the stalks decay in the autumn, and new ones arise in the spring. This is propagated by seeds, which should be sown upon a bed of light earth in the spring, and when the plants are fit to remove, they should be either transplanted to the places where they are to remain, or into pots where they may stand to get more strength, before they are planted in the full ground. After the plants are well rooted, they will require no other care but to keep them clear from weeds. And if the winter should prove very severe, it will be proper to cover the ground about them with old tanners bark to keep out the frost; but they will endure the cold of our ordinary winters very well, and will produce their flowers and ripen their seeds annually.

The fifth sort will not live through the winter in the open air in England, so the seeds should be sown in the same manner as those of the other sorts; and when the plants are fit to remove, they should be each planted into a small pot filled with light earth, and placed in the shade till they have taken new root; then they may be removed to a sheltered situation, and mixed with other hardy exotic plants. As the plants advance in their growth, so they will require larger pots, and must be treated in the same way as other exotic plants; in the autumn they must be removed into the green-house, and placed with Myrtles and the other kinds of plants, which only require protection from hard frost, but must have as much free air as possible in mild weather.

LAVENDULA. Tourn. Inst. R. H. 198. tab. 93. Lin. Gen. Plant. 630. Lavender; in French, *Lavande*. [It takes its name of *Lavando*, *Lat.* washing, because it was used to be thrown into baths for the fragrantcy of the scent; or because used in lye, to give a fragrantcy to linen; and because it is very good to wash the face with, and give it both beauty and a grateful scent.]

The CHARACTERS are,

The flower hath an oval permanent empalement of one leaf, which is obscurely indented at the brim. The flower is of the lip kind, with one petal, having a cylindrical tube longer than the empalement, but spreading above;

the upper lip is large, bifid, and open; the under lip is cut into three equal segments. It hath four short stamina situated within the tube of the petal, two being shorter than the other, terminated by small summits. It hath a germen divided in four parts, supporting a slender style the length of the tube, crowned by an obtuse indented stigma. The germen afterward turns to four oval seeds, sitting in the empalement.

This genus of plants is ranged in the first section of Linnæus's fourteenth class, intitled *Didynamia Gymnospermia*, which includes those plants whose flowers have two short and two longer stamina, and have four naked seeds sitting in the empalement.

The SPECIES are,

1. **LAVENDULA** (*Spica*) foliis lanceolatis integerrimis spicis nudis. Hort. Cliff. 303. *Lavender with entire spear-shaped leaves and naked spikes.* *Lavendula latifolia.* C. B. P. 216. *Broad-leaved Lavender.*
2. **LAVENDULA** (*Angustifolia*) foliis lanceolato-linearibus, spicis nudis. *Lavender with spear-shaped narrow leaves, and naked spikes.* *Lavendula angustifolia.* C. B. P. 216. *Narrow-leaved Lavender.*
3. **LAVENDULA** (*Multifida*) foliis duplicato-pinnatifidis. Vir. Cliff. 56. *Lavender with leaves doubly wing-pointed.* *Lavendula folio dissecto.* C. B. P. 216. *Lavender with a cut leaf.*
4. **LAVENDULA** (*Canariensis*) foliis duplicato-pinnatifidis hirsutis, spicis fasciculatis. *Lavender with doubly wing-pointed hairy leaves, and spikes of flowers growing in clusters.* *Lavendula folio longiore tenuius & elegantius dissecto.* Tourn. Inst. R. H. 198. *Lavender with a longer, narrower, and more elegant cut leaf.*

The first sort is cultivated in several of the English gardens, and has been generally known by the title of *Spike*, or *Lavender Spike*; the leaves of this sort are much shorter and broader than those of the common *Lavender*, and the branches are shorter, more compact, and fuller of leaves. This sort doth not often produce flowers, but when it does, the flower-stalks are garnished with leaves very different from those on the other branches, approaching nearer to those of the common sort, but are broader; the stalks grow taller, the spikes of the flowers are larger, the flowers are smaller, and are in looser spikes. It generally flowers a little later in the season. This has been frequently confounded with the common *Lavender*, and has been supposed the same species, but is undoubtedly a different plant.

This I believe to be the same with what Dr. Morisson calls *Lavendula latifolia sterilis*, for the plants will continue several years without producing flowers; during which time they have a very different appearance from those of the common *Lavender*, as those branches of the same plant always have which do not flower; but I have planted slips taken from those flowering branches with narrow leaves, and others from those with the broad leaves, but have always found the plants so propagated return to their original sort, the cuttings with the narrow leaves have become broad again.

The second sort is the common *Lavender*, which is so well known as to require no description. Both these sorts flower in July, at which time the spikes of the second sort are gathered for use; there is a variety of this with white flowers.

These are propagated by cuttings or slips; the best season for which is in March, when they should be planted in a shady situation, or at least they should be shaded with mats until they have taken root, after which they may be exposed to the sun; and when they have obtained strength, may be removed to the places where they are designed to remain. These plants will abide much longer in a dry, gravelly, or stony soil, in which they will endure our severest winters; though they will grow much faster in the summer, if they are planted upon a rich, light, moist soil, but then they are generally destroyed in winter; nor are the plants half so strong scented, or fit for medicinal uses, as those which grow upon the most barren rocky soil.

These

LAU

These plants were formerly in use to make edgings to borders in gardens, for which purpose they are by no means proper, for they will grow too large for such designs; and if they are often cut in very dry weather, they are subject to decay; and in hard winters they are very often killed, so that the edging will not be complete: besides, these plants greatly exhaust the goodness of the soil, whereby the plants in the borders will be deprived of their nourishment; so that they should never be planted in a fine garden amongst other choice plants and flowers, but rather be placed in beds in the physic-garden, or in any part of the kitchen-garden, if the soil is dry.

The third sort grows naturally in Andalusia; this is an annual plant, which rises with an upright branching stalk two feet high; the stalks are woolly, and garnished with hoary leaves growing opposite, which are cut into many divisions to the midrib; these segments are again divided on their borders toward the top, into three obtuse segments, so that they end in many points. The foot-stalk of the flower is continued from the end of the branches, which is naked, and about six inches long, having four corners or angles, and is terminated by a close spike of flowers about one inch long; the spike has the rows of flowers twisted spirally: under this spike there are commonly two small ones proceeding from the side of the stalk, at about an inch distance from the middle spike. This sort flowers in July, and the seeds ripen in autumn. There are two varieties of this, one with blue, and the other with white flowers.

This sort is sown every spring on borders or beds of light fresh earth, and when the plants come up, they may be transplanted into other borders of the flower-garden, or into pots, to remain for good; where they will require no farther care, but to keep them clean from weeds. These are pretty plants to place in large borders, amongst other plants, for variety, but they are never used with us; they may also be preserved over the winter, if placed in a green-house in autumn; but they never continue longer than two years with us, and many times (if they have produced seeds the first year) they will not continue longer. Nor do those plants which are thus preserved, appear handsome the following summer, so that, unless in bad seasons, when the seeds do not ripen in the open air, it is not worth while to preserve the plants. If the seeds of this sort are permitted to scatter, the plants will come up the following spring without care, and may be treated in the manner before directed.

The fourth sort grows naturally in the Canary Islands, from whence the seeds were sent to the Bishop of London, which were sown in his Lordship's garden at Fulham, where this plant was first raised. This rises with an upright, branching, square stalk four feet high, garnished with leaves which are longer, and cut into narrower segments than those of the third sort. They are of a lighter green and almost smooth; the naked flower-stalk is also much longer than those of the former, and terminated with a cluster of spikes of blue flowers; at two or three inches below these, are two small spikes of flowers, standing one on each side the stalk. The flowers are smaller than those of the common Lavender, but are of the same shape. This sort is tenderer than either of the former, so the seeds of this must be sown on a moderate hot-bed in the spring; and when the plants come up, they should be each planted into a separate small pot filled with light earth, and plunged into another hot-bed, to bring the plants forward; and in the beginning of June, they should be inured to the open air, when they should be placed in a sheltered situation toward the end of that month; in July the plants will flower, and if the autumn proves warm, the seeds will ripen in September; but when they do not perfect seeds, the plants may be preserved through the winter in a good green-house, where they will produce flowers most part of that season, whereby good seeds may be obtained.

LAUREOLA. See THYMELÆA.

LAUROCERASUS. See PADUS.

LAURUS. Tourn. Inst. R. H. 597. tab. 367. Lini. Gen. Plant. 452. The Bay-tree; in French, *Laurier*.

The CHARACTERS are,

It hath male and hermaphrodite flowers on different plants, the male flowers have no empalement: they have one petal, which is cut into six segments at the top, and nine stamina which are shorter than the petal, standing by threes, terminated by slender summits. The hermaphrodite flowers have no empalement; they have one petal, which is slightly cut into six segments at the top. In the bottom is situated an oval germen, supporting a single style of the same length with the petal, crowned by an obtuse stigma, attended by six or eight stamina: there are two globular glands, standing upon very short foot-stalks, fixed to the base of the petal. The germen afterward becomes an oval berry with one cell, inclosing one seed of the same form.

This genus of plants is ranged in the first section of Linnæus's ninth class, intitled Enneandria Monogynia, which includes those plants whose flowers have nine stamina and one style; but it should be ranged in his twenty-second class, which includes those plants whose male and female flowers are upon different plants.

The SPECIES are,

1. LAURUS (*Nobilis*) foliis lanceolatis venosis perennantibus, floribus quadrifidis dioeciis. Hort. Cliff. 105. Bay-tree with evergreen, spear-shaped, veined leaves, and flowers cut into four points, which are male and female on different plants. *Laurus latifolia* Discoridis. C. B. P. The broad-leaved Bay of Dioscorides.
2. LAURUS (*Undulatis*) foliis lanceolatis venosis perennantibus, marginibus undatis. Bay-tree with evergreen spear-shaped leaves, which are veined and waved on their edges. *Laurus vulgaris folio undulato*. H. R. Par. Common Bay-tree with waved leaves.
3. LAURUS (*Tenuifolia*) foliis lineari-lanceolatis venosis perennantibus, floribus quinquefidis dioeciis. Bay-tree with narrow spear-shaped leaves which are evergreen and veined, flowers cut into five points, which are male and female on different plants. *Laurus tenuifolia*. Tab. Icon. 925. Narrow-leaved Bay.
4. LAURUS (*Indica*) foliis venosis lanceolatis perennantibus planis, ramulis tuberculatis cicatricibus, floribus racemosis. Hort. Cliff. 154. Bay-tree with evergreen, veined, spear-shaped, plain leaves, branches having tubercles and cicatrices, and flowers growing in bunches. *Laurus Indica*. Ald. Hort. Farnes. 61. The Indian Bay.
5. LAURUS (*Borbonia*) foliis venosis lanceolatis calycibus fructus baccatis. Lin. Sp. 529. Bay-tree with veined spear-shaped leaves, and the empalement becomes berries. *Laurus Caroliniensis*, foliis acuminatis, baccis cæruleis, pediculis longis rubris insidentibus. Catesb. Carol. 1. p. 63. Carolina Bay-tree with pointed leaves, and blue berries sitting upon long red foot-stalks.
6. LAURUS (*Benzoin*) foliis ovato-lanceolatis obtusis integris annuis. Bay-tree with oval, obtuse, spear-shaped, entire leaves, which are annual. *Arbor Virginiana*, citreæ vel limonii folio, Benzoinum fundens. Hort. Amst. 1. p. 168. The Benjamin-tree.
7. LAURUS (*Sassafras*) foliis integris trilobisque. Hort. Cliff. 154. Bay-tree with entire leaves, or having three lobes. *Cornus mas odorato*, folio trifido, margine plano, sassafras dicta. Pluk. Alm. 120. The Sassafras.
8. LAURUS (*Enervius*) foliis venosis oblongis acuminatis annuis, subtus rugosis. Bay-tree with oblong, acute-pointed, veined, annual leaves, which are rough on their under side. *Laurus foliis lanceolatis enervibus annuis*. Flor. Virg. 159. Bay-tree with spear-shaped, winged, unruined, annual leaves.

13. LAURUS (*Persea*) foliis venosis ovatis coriaceis perennantibus, floribus corymbosis. Lin. Sp. 529. *Bay-tree with oval, thick, veined leaves, which continue through the year, and flowers growing in a corymbus. Persea. Clus. Hist. 1. p. 2.*

The first sort is the broad-leaved Bay, which grows naturally in Asia, Spain and Italy; from all those places I have received the berries several times. This is almost too tender to thrive in the open air in England, for in severe winters they are frequently killed, or their branches are so much injured as to appear so for a long time; therefore they are generally planted in tubs, and removed into the green-house in winter. The leaves of this sort are much broader than those of the common Bay, and are smoother: there are male and female plants of this, as there are also of all the other sorts.

The second is the common Bay; of this there are plants with plain leaves, and others which are waved on their edges, but they seem to be the same species; for the young plants which I have raised from the berries of one, have been a mixture of both sorts; but this is undoubtedly a different species from the first, for this sort thrives well in the open air, and is seldom hurt, except in very severe winters; whereas the first will scarce live abroad, while young, in common winters, without shelter.

The third sort hath very long narrow leaves which are not so thick as those of the two former, and are of a light green; the branches are covered with a purplish bark, and the male flowers come out in small clusters from the wings of the leaves sitting close to the branches. This sort is too tender to thrive in the open air in England, so the plants are generally kept in pots or tubs, and housed in winter as the first sort.

The fourth sort grows naturally at Madeira and the Canary Islands, from whence it was formerly brought to Portugal, where it has been propagated in so great plenty, as to appear now as if it was a native of that country. In the year 1620, this plant was raised in the Farnesian garden, from berries which were brought from India, and was supposed to be a bastard sort of Cinnamon. This grows to the height of thirty or forty feet in temperate countries, but it is too tender to thrive in the open air in England, so the plants are kept in pots and tubs, and removed into the green-house in winter.

The leaves of this sort are much larger than those of the common Laurel; they are thick, smooth, and of a light green, the foot-stalks inclining to red; the branches are regularly disposed on every side, and the male flowers are disposed in long bunches; they are of a whitish green colour; the berries are much larger than those of the other sorts. It is called by some the Royal Bay, and by others the Portugal Bay.

The fifth sort grows naturally in Carolina in great abundance, where it is called the Red Bay; it also is found in some other parts of America, but not in so great plenty. In some situations near the sea, this rises with a strait trunk to a considerable height, and their stems are large, but in the inland parts of the country they are of an humbler stature. The wood of this tree is much esteemed, being of a fine grain, so is of excellent use for cabinets, &c.

The leaves of this sort are much longer than those of

L A U

the common Bay, and are a little woolly on their under side, their edges are a little reflexed; the veins run transversely from the midrib to the sides, and the male flowers come out in long bunches from the wings of the leaves. The female trees produce their flowers in loose bunches, standing upon pretty long foot-stalks, which are red; these are succeeded by blue berries sitting in red cups.

This sort is also too tender to thrive in the open air in England; for although some plants have lived abroad in a mild winter, which were planted in a warm situation, yet the first sharp winter has destroyed them, so that these plants must be kept in pots or tubs, and housed in winter like the former.

These five sorts may be propagated by layers, and the common sort is generally propagated by suckers; but those plants never keep to one stem, but generally send out a great number of suckers from their roots, and form a thicket, but do not advance in height; therefore the best way to have good plants, is to raise them from the berries, when they can be procured, for the plants which come from seeds, always grow larger than the others, and do not put out suckers from their roots, so may be trained up with regular stems. The best way is to sow the berries in pots, and plunge them into a moderate hot-bed, which will bring up the plants much sooner than if they are sown in the full ground, so they will have a longer time to get strength before winter; but the plants must not be forced with heat, therefore they should be inured to bear the open air the beginning of June, into which they should be removed, where they may remain till autumn; then the pots should be placed under a common frame, that the plants may be protected from hard frost, but in mild weather they may enjoy the free air; for while the plants are so young, they are in danger of suffering in hard frost, even the common sort of Bay. The spring following, those sorts which will not live in the open air, should be each transplanted into separate pots; but the common sort may be planted in nursery-beds six inches asunder each way, where they may grow two years, by which time they will be fit to plant where they are designed to grow. The other sorts must be constantly kept in pots, so should every year be new potted, and as they advance in growth, they must have larger pots. As these plants require shelter in winter, a few of each sort will be enough for a large green-house.

The common Bay will make a variety in all ever-green plantations; and as it will grow under the shade of other trees, where they are not too close, so it is very proper to plant in the borders of woods, where it will have a good effect in winter.

The sixth sort grows naturally in North America, where it rises to the height of ten or twelve feet, dividing into many branches, garnished with oval spear-shaped leaves near three inches long, and one inch and a half broad, smooth on their upper surface, but with many transverse veins on their under side; these leaves fall off in the autumn like other deciduous trees. The flowers I have but once seen, those were all male, and of a white herbaceous colour; but if I remember right, they had but six stamina in each.

The Sassafras-tree is also very common in most parts of North America, where it spreads greatly by its roots, so as to fill the ground with suckers wherever they are permitted to grow; but in England this shrub is with difficulty propagated. In America it is only a shrub, seldom rising more than eight or ten feet high; the branches are garnished with leaves of different shapes and sizes, some them are oval and entire, about four inches long and three broad; others are deeply divided into three lobes; these are six inches long, and as much in breadth from the extremity of the two outside lobes; they are placed alternately upon pretty long foot-stalks, and are of a lucid green; these fall off in the autumn; and in the spring, soon after the leaves begin to come out, the flowers appear just below them, upon slender foot-stalks, each sustaining

L A U

sustaining three or four small yellow flowers, which have five oval concave petals, and eight stamina in the male flowers, which are upon different plants from the hermaphrodite flowers, which have an oval germen, that afterward becomes an oval berry, which, when ripe, is blue, but those plants do not produce fruit in England.

The eighth sort grows naturally in North America, in swampy lands; this rises with a shrubby branching stalk eight or ten feet high, covered with a purple bark. The leaves are placed opposite, and are near two inches long and one broad, smooth on their upper side, but are veined on their under, where they are rough. This hath not as yet produced flowers here, but the berries which were sent me from Maryland were red, and nearly the size and shape of the common Bay-berry.

The Camphire-tree grows naturally in Japan, and in several parts of India, and also at the Cape of Good Hope, where it rises to a tree of middling stature, dividing into many small branches, garnished with oval spear-shaped leaves, smooth on their upper side, having three longitudinal veins which unite above the base; if these are bruised, they emit a strong odour of Camphire, as also the branches when broken. These are male and hermaphrodite on different trees; I have only seen those of the male, which has flowered plentifully in England; these were small, and composed of five concave yellow petals, very like those of the Sassafras-tree, and were produced three or four upon each foot-stalk, in like manner.

The tenth sort was discovered by the late Dr. Houstoun at La Vera Cruz; this rises with a woody stalk to the height of twenty feet, dividing into many branches, which are covered with a gray rough bark; at the extremity of the branches are produced the foot-stalks, which are unequal in length, but divide into several smaller, each sustaining a cluster of small white flowers, which are collected into a head or small umbel, having one general involucre; these are male and hermaphrodite on different trees. The hermaphrodite flowers are succeeded by oval berries, not quite so large as those of the common Bay. The leaves of this tree are about two inches long and one broad, rounded at the top and entire, standing upon very short foot-stalks.

The Sassafras-tree is commonly propagated by the berries, which are brought from America; but these berries generally lie in the ground a whole year, and sometimes two or three years before they grow, when they are sown in the spring; therefore the surest method of obtaining the plants will be, to get the berries put into a tub of earth soon after they are ripe, and sent over in the earth; and as soon as they arrive, to sow the berries on a bed of light ground, putting them two inches in the earth; and if the spring should prove dry, the bed must be frequently watered, and shaded from the great heat of the sun in the middle of the day; with this management many of the plants will come up the first season, but as a great many of the berries will lie in the ground till the next spring, so the bed should not be disturbed, but wait until the season after, to see what will come up. The first winter after the plants come up, they should be protected from the frost, especially in the autumn; for the first early frost at that season is apt to pinch the shoots of these plants, which, when young, are tender and full of sap, so will do them more injury than the severe frost of the winter; for when the extreme part of the shoots are killed, it greatly affects the whole plant.

When the plants have grown a year in the seed-bed, they may be transplanted into a nursery, where they may stand one or two years to get strength, and may then be transplanted into the places where they are to remain for good.

There have been some of these plants propagated by layers, but these are commonly two, and sometimes three years before they put out roots; and if they are not duly watered in dry weather, they rarely take

L A U

root; so that it is uncertain, whether one in three of these layers do succeed, which makes these plants very scarce in England at present.

The wood of this shrub is frequently used to make tea, which is esteemed a great antiscorbutic; and in Carolina they frequently give a decoction of the wood and leaves in intermitting fevers; but the flowers of the shrub are gathered, and dried by the most curious, and are used for tea.

The Benjamin-tree, as it is falsely called, may be propagated in the same manner as the Sassafras, by sowing of the berries: these generally lie long in the ground, so that unless they are brought over in earth, in the same way as before directed, they often fail, or at least remain long in the ground; but this is now frequently propagated by layers in England, which put out roots pretty freely, when the young shoots are chosen to make layers.

The eighth sort is also a native of the same country with the last, and may be propagated by seeds in the same manner as those, and require the same treatment. This may also be propagated by layers, which put out roots pretty freely; and as the shrubs do not produce seeds in England, so this is the best method to propagate them.

These three sorts will live in the open air in England, but the Sassafras is often injured by very severe frosts, especially if they are in an exposed situation; therefore these plants should have a warm situation and a loose soil; and in moist ground this, and also the eighth sort, will thrive much better than in a dry soil; for when they are planted on a hot gravelly soil, they frequently die in summer when the season proves dry. They are all of them now much cultivated in England, to add to the variety of shrubs, but they are not very ornamental plants; though indeed the Sassafras makes a good appearance in summer, when it is fully clothed with its large leaves, which being of different shapes, makes an agreeable variety, when intermixed with shrubs of the same growth.

The Camphire-tree is very near a-kin to the Cinnamon-tree, from which it differs in the leaves, those of the Cinnamon-tree having three ribs running longitudinally from the foot-stalk to the point, where they soon diminish; whereas the ribs of the leaves of this tree are small, and extend toward the sides, and have a smooth shining surface: they are both male and hermaphrodite in different trees.

In Europe this tree is propagated by layers, which are generally two years, and sometimes longer, before they take root, so that the plants are very scarce; and as all those which I have seen flower are male trees, so there can be no hopes of procuring seeds from them here: but if the berries of this, and also of the Cinnamon-tree, were procured from the places of their growth, and planted in tubs of earth, as hath been directed for the Sassafras-tree, there may be a number of these plants procured in England: and if they were sent to the British colonies in America, they might be there cultivated, so as to become a public advantage; especially the Cinnamon-tree, which will grow as well in some of our islands in the West-Indies, as it does in the native places of its growth, and in a few years the trees might be had in plenty; for they propagate easily by the berries, as the French experienced in their American islands. The Portuguese brought some of the Cinnamon-trees from the East-Indies, and planted them on the island of Princes, on the coast of Africa, where they now abound, having spread over a great part of the island; there is also one tree now growing at the Madeiras, which I have been informed is a male, so never produces berries.

The Camphire-tree does not require any artificial heat in winter, so that if they are placed in a warm dry green-house they will thrive very well. During the winter season they must be sparingly watered, and in the summer they should be placed abroad in a warm situation, where they may be defended from strong winds, and not too much exposed to the direct rays

of

L A W

of the sun; but during this season, they must be frequently refreshed with water.

They may be propagated by laying down the young branches in autumn, which should be treated in the same manner as is before directed for the Benjamin.

The tenth sort requires a stove to preserve it through the winter in England; this is propagated by seeds, which must be procured from the country where it grows naturally.

This plant requires the same treatment as the Coffee-tree, so should be planted in a stove, with that and other tender plants of those warm countries, and always remain there.

The eleventh and twelfth sorts have been generally confounded by most, if not all the writers who have treated of them; though their bark, which is the material part of these trees in use, is pretty easily distinguished by the dealers in these commodities.

Dr. Linnæus is certainly mistaken in referring the latter to the figure of Dr. Burman, which he has given in his History of Ceylon plants, by the title of *Cinnamomum perpetuo florens*, &c. which is a true representation of the male Cinnamon-tree, and is not the *Cassia Lignea*; but as there are plants of all these sorts now in the British Islands of America, so we may hope soon to have their species better ascertained.

The plants of both these kinds are not so tender as most people do imagine, and the treating of those plants which have been brought to England so tenderly has destroyed them; for so far as I have made trial of their culture it has appeared, that great heat is very prejudicial to them; therefore I would advise those persons who may have any of the plants come under their care, to treat them in a different-manner, otherwise there will be little hopes of keeping them; for when the plants have taken new root in the pots, they should in summer be placed in a glass-case, where they may have plenty of air in warm weather, and in winter placed in a stove kept moderately warm.

L A U R U S A L E X A N D R I N A. See **R U S C U S**.

L A U R U S T I N U S. See **T I N U S**.

L A W N is a great plain in a park, or a spacious plain adjoining to a noble seat.

As to the dimensions of it, it should be as large as the ground will permit; but never less, if possible, than thirty or forty acres; but this is to be understood of Lawns in large parks, for in gardens a Lawn of six or eight acres is a reasonable size for gardens of a moderate extent, ten or twelve acres for those of the largest size.

As to the situation of a Lawn, it will be best to be in the front of the house, and to lie open to the neighbouring country, and not pent up too much with trees.

If the house front the east, or south-east, it will be most convenient, because the rooms will be shaded in the afternoon, and so the objects to be viewed from the house will be much better seen, by the sun's shining upon them at that time of the day; for if the best room of the house front the Lawn, as it always should do, the afternoon being the most usual time for people of fashion to solace themselves in such rooms, the sun will not be offensive to those rooms, nor will the prospect be interrupted, but rendered more pleasant; whereas, were it on the west side of the house, the sun, by shining from the object, and directly against those rooms, would, by both, hinder the prospect, for the generality of prospects are most pleasant when the sun shines upon the objects.

Besides, there is another inconvenience, if the Lawn be on the west side of the house, it will give the more way to the west wind (which is commonly the greatest) to injure the house, by its having a free passage to it.

If the Lawn be on the south side of the house, it may do well enough, for the reasons before-mentioned, for the sun's rays being then darted obliquely, will not so much interrupt the prospect, and the sun shining most part of the day on that side of the house, will still add to the beauty of that front, which ought to

L A W

be the best front in the house, therefore a Lawn on that side will much help the prospect of the house.

But the most desirable aspect for a Lawn is that of the south-east, which is generally the most favourable point in England; for as the sun rises upon the front of the house facing this point, so it will add a cheerfulness to the rooms in the morning, and by noon the rays will be oblique to this front, and in the afternoon will have entirely left these apartments.

It will not be at all convenient to have the Lawn on the north side of the house, because it will lay the house too open to the cold north winds, &c. therefore it will be more eligible to plant wildernesses and woods on the west and north sides of the house, by way of screen to it, provided these do not shut out agreeable objects.

As to the figure of the Lawn, some contend for an exact square, others an oblong square, some an oval, and others a circular figure; but neither of these are to be regarded, for it will be much better if contrived so as to suit the figure of the ground; and as there should be trees planted for shade on the boundaries of the Lawn, so the sides may be broken by irregular plantations of trees; for if there are not some good prospects beyond the Lawn, it will be proper to have it bounded on every side by plantations, which may be brought round pretty near to each end of the house, so that persons may soon get into shade, which is a very desirable thing in hot weather; for where that is wanting, few persons care to stir abroad when the sun shines warm.

If in the plantations round the Lawn, the trees are placed irregularly, some breaking much forwarder on the Lawn than others, and not crowded too close together, they will make a much better appearance than any regular plantations can possibly do; and if there are varieties of trees properly disposed, they will have a good effect; but it should be observed, that no other but those which make a fine appearance, and that grow large, strait, and handsome, should be admitted here, as they are placed in the constant view from the house.

Many persons have preferred the Lime-tree for this purpose, on account of their regular growth; but as the leaves of this tree often change their colour, and begin to fall very soon in autumn, occasioning a great litter in the garden; and from the end of July the trees make but an indifferent appearance, so they are not to be esteemed for these plantations.

The Elm, Oak, Beech, and Chestnut, among the deciduous trees, are to be preferred to all others, as they keep their leaves late in autumn; and these are all of them large growing trees, so are very proper for this purpose.

If there are some clumps of Evergreen trees intermixed with the deciduous trees in this plantation, if they are properly disposed, it will add to the beauty, especially in the winter season; the best sorts for this purpose are Lord Weymouth's Pine, the Silver and Spruce Firs, which will grow fast, and become large trees; and as the two latter sorts always grow pyramidically, so they will have a good effect to the sight, if they are rightly placed, but they should not be intermixed in the same clumps with the deciduous trees; but as these generally feather out their branches near the ground, they should be planted where they do not obstruct the view of any distant objects.

But as most persons who take pleasure in beautifying their seats in the country, are in haste for shade, they generally plant the trees too close together, and often in such a manner as to render it difficult when the trees are advanced to reduce their number, without injury to the design; therefore those trees should be first planted, which are designed to remain, and then there may be some few others planted for present shade, which may afterward be taken away. When persons who are beautifying their seats meet with full grown trees on the spot, it is a great pleasure, for these should not be destroyed, if they can possibly stand without prejudice.

L A W.

L A Y

LAWSONIA. Lin. Gen. Plant. 433. Henna. Ludw.

143.

The CHARACTERS are,

The flower has a small permanent empalement, divided into four parts at the top. The flower is composed of four oval spear-shaped petals, which spread open, and eight slender stamina the length of the petals, which stand by pairs between them, terminated by roundish summits. It hath a roundish germen, supporting a slender permanent style, crowned by a beaded stigma. The germen afterward becomes a globular capsule ending in a point, having four cells, filled with angular seeds.

This genus of plants is ranged in the first section of Linnæus's eighth class, intitled Oëandria Monogynia, which includes those plants whose flowers have eight stamina and one style.

The SPECIES are,

1. LAWSONIA (*Inermis*) ramis inermibus. Flor. Zeyl. 134. *Lawsonia whose branches have no spines.* Ligustrum Ægyptiacum latifolium. C. B. P. 476. *Broad-leaved Egyptian Privet, called Albenna, or Henna, by the Arabians.*

2. LAWSONIA (*Spinosa*) ramis spinosis. Flor. Zeyl. 134. *Lawsonia with prickly branches.* Rhamnus Malabaricus MAIL-ANSKI. Pluk. Alm. 38. tab. 220. *Malabar Buckthorn, called Mail-anski.*

The first sort grows naturally in India, Egypt, and other warm countries, where it rises with a shrubby stalk eight or ten feet high. The branches come out by pairs opposite; these are slender, and covered with a whitish yellow bark, and garnished with oblong small leaves of a pale green, ending in acute points, placed opposite. The flowers are produced in loose bunches at the end of the branches; they are of a gray or dirty white colour, and are composed of four small petals which turn backward at the top. The flowers are succeeded by roundish capsules with four cells, filled with angular seeds.

The leaves of this shrub are much used by the Egyptian women to colour their nails yellow, which they esteem an ornament.

The second sort grows naturally in both Indies, for I have received specimens of it from the Spanish West-Indies, where it was found growing naturally in great plenty.

This rises with a woody trunk eighteen feet high or more. The wood is hard and close, covered with a light gray bark. The branches come out alternate, and are garnished with oblong oval leaves, which stand without order; and at the joints where the leaves are placed, come out single, strong, sharp thorns. The flowers are produced in loose bunches from the side of the branches; they are of a pale yellow colour, and of a disagreeable scent; they have four petals, which spread open; between each of these are situated two pretty strong stamina, terminated by roundish summits. After the flowers are past, the germen becomes a roundish capsule with four cells, including many angular seeds.

These plants are both propagated by seeds, which should be sown on a hot-bed early in the spring, that the plants when they come up may have time to get strength before winter. When the plants are fit to remove, they should be each planted in a small pot filled with light sandy earth, and plunged into a hot-bed of tanners bark, where they must be screened from the sun till they have taken new root; then their treatment should be the same as that of the Coffee-tree, with this difference only, not to let these plants have so much water; but especially in the winter, during which season it should be given to them very sparingly, for by over-watering these plants I have known many of them destroyed; these plants are too tender to thrive in the open air in England, so they must constantly remain in the stove, but in hot weather they should have plenty of free air admitted to them.

LAYERS. Many trees and shrubs may be propagated by Layers,* which do not produce seeds here, so are not easily increased by any other method.

L A Y

This is to be performed by sitting the branches a little way upward, and laying them under the mould about half a foot; the ground should first be well digged and made very light, and after they are laid they should have a little water given them.

If they do not comply well in the laying of them down, they must be pegged down with a forked stick cut in form of a hook to keep them down; if the Layers have taken sufficient root by the next winter, they must be cut off from the main plants, and planted in the nursery, as is directed about seedlings.

Some twist the branch or bare the rind, and if it be out of the reach of the ground, they fasten a tub or basket near the branch, which they fill with good mould, and lay the branch in it.

Laying of Trees.

This operation is thus performed:

1st, Take some of the most flexible boughs and lay them into the ground about half a foot deep in fine fresh mould, fastening them down with forked sticks, leaving them with the end of the Layer about a foot or a foot and a half out of the ground, and keep them moist during the summer season, and they will probably have taken root and be fit to remove in autumn, and if they have not by that time taken root they must lie longer.

2dly, Tie a piece of wire hard round the bark of the bough, at the place you intend to lay in the ground, and twist the ends of the wire, so that they may not untie, and prick the place above the wire through the bark, with an awl in several places, and then lay it in the ground as before directed; this will often succeed when the other fails.

3dly, Cut a slit upwards at a joint, as is practised in laying of Carnations, which by gardeners is called tonguing the Layers.

4thly, Twist the part of the branch designed to lay in the ground like a withy, if it is pliable, and lay it into the ground as directed in the first way of laying.

5thly, Cut a circle almost round about the bough (that is designed to be laid) half an inch, at the place that is most convenient to lay into the ground, and manage it as is directed in the first method of laying. The season for laying hardy trees that shed their leaves is in October, but for such as are tender in the beginning of March; for Evergreens, June or July are good seasons.

Though Layers may be laid at any time in the year, yet the before-mentioned seasons are most proper, for the reasons following, because they have the whole winter and summer to prepare and draw root; for at these times of the year the sun has sufficient power on the sap of the tree to feed the leaf and bud, but has not power sufficient to make a shoot.

And if that small quantity of sap that does arise be hindered, as it will by some of the preceding ways of laying, the leaves and buds will gently crave of the Layer, and by that means will prepare the Layer to take root, or put forth roots a little to maintain itself, finding it cannot have it from the mother plant. And therefore, because it wants but little nourishment at that time of the year, it is better to lay Layers of trees, or to set cuttings than at other times, either in the autumn, when the sap stirs but little, or in the spring when it begins to rise, because it is then apt to come too suddenly to draw sap from the Layer, before the Layer has drawn or prepared for root; but for some sorts the middle of summer is best.

However, the spring or summer may do well for small plants, because such plants being but short-lived draw root the quicker.

If you would lay young trees from a high standard, the boughs of which cannot be bent down to the ground, then you must make use of Osier baskets, boxes, or pots, filled with fine mould, mixed with a little rotten Willow dust, which will keep moisture to assist the Layer in taking root; this basket, box, &c. must be set upon a post or tressel, &c. and the bough must

LEA

be laid according to either of the four first ways of laying, but too much head must not be left on, lest that be injured by the wind, or by its own motion rub off the tender root; and the smaller the boughs are, the less way they should be left out of the ground, and care must be taken to keep them clear from weeds.

The harder the wood of the tree is, the young shoots will take root best; but if the wood be soft, the older boughs will take root the best.

There are many kinds of trees and plants which will not put out roots from their woody branches, though laid down with the utmost care; yet if the young shoots of the same year are laid in July, they will often put out roots very freely, so that when any plants are found difficult to propagate by Layers in the common way, they should be tried at this season; but as these shoots will be soft and herbaceous, they must not have too much wet, for that will cause them to rot; therefore it will be a better method to cover the surface of the ground over the Layers with Moss, which will prevent the ground from drying too fast, so that a little water now and then will be sufficient.

L. F. A. V. E. S. A Leaf is defined to be a part of a plant extended into length and breadth, in such a manner as to have one side distinguishable from the other; they are properly the most extreme part of a branch, and the ornament of the twigs, and consist of a very glutinous matter, being furnished every where with veins and nerves; one of their offices is, to subtilize and give more spirit to the abundance of nourishing sap, and to convey it to the little buds.

We shall first consider the distinctions which are made by botanists in their definitions of the shape and form of Leaves in their titles and descriptions of plants, and afterward consider their uses in vegetation.

The Leaf of a plant or tree is distinguished from that of flowers, the first is called *Folium* in Latin, and the other *Petalum*; therefore what is to be understood here of Leaves, are those which are ranged on the branches and stalks of plants, and have no connection with the flower.

These Leaves are either simple or compound.

Simple Leaves are those of which the foot-stalk or petiole supports but one, compound are those of which the foot-stalk sustains many Leaves or small foliola.

Simple Leaves differ in respect to circumscription, angles, sinus, apices, margin, superficies and substance; circumscription considers the form of the circumference of Leaves where there are no angles or sinuations; in which respect Leaves are,

Orbulate, or round Leaves (*Orbiculatum*) are such whose breadth are equal to their length, and every part of their edges equally distant from the center, as in fig. 1.

A roundish Leaf (*Subrotundum*) when the Leaf is nearly orbiculate, as in fig. 2.

An oval or egg-shaped Leaf (*Ovatum*) when the length of the Leaf exceeds the breadth, and the base or lower part of it forms a segment of a circle; but the upper extremity is not in proportion, but smaller, as in fig. 3.

An obverse oval Leaf is one whose foot-stalk is fixed to its smaller end.

An oval or elliptic Leaf (*Ovale sive ellipticum*) is one whose length exceeds its breadth, and both ends are narrower than the segments of circles, as fig. 4.

A parabolical Leaf (*Parabolicum*) is one whose length exceeds its breadth, and is narrowed from the base upward; so becomes half egg-shaped, fig. 5.

A spatulated Leaf (*Spatulatum*) is of a roundish figure, but narrow at the base, and linearly lengthened, fig. 6.

A wedge-shaped Leaf (*Cuneiforme*) is one whose length exceeds the breadth, and is narrowed to the base, fig. 7.

An oblong Leaf (*Oblongum*) is one whose length greatly exceeds its breadth, and each extremity is narrower than a segment of a circle, fig. 8.

LEA

A spear-shaped or spear-pointed Leaf (*Lanceolatum*) is oblong, and grows narrower toward both ends, and terminates in a point, fig. 9.

A linear Leaf (*Lineare*) is one whose two sides run almost parallel to each other; they are usually narrow, and somewhat broader in the middle than at the two ends, fig. 10.

A chaffy Leaf (*Acrosum*) is when the linear Leaf stays on the tree, and is evergreen, as in the Fir, Yew, &c. fig. 11.

An awl-shaped Leaf (*Subulatum*) is one which is linear below, but gradually contracting towards the top, fig. 12.

A triangular Leaf (*Triangulare*) is when the disk is surrounded by three prominent angles, fig. 13.

A quadrangular and quinquangular Leaf, only differ from the former in the number of their sides or angles, fig. 14.

A deltoide Leaf is one with four angles, of which those of the extremities are farther distant from the center than those of the sides, fig. 15.

A round Leaf (*Rotundum*) is one without any angles.

A sinus (or Hollow) is used to express those openings or cavities in Leaves which distinguish them into parts.

A kidney-shaped Leaf (*Reniforme*) is of a roundish figure, and hollowed a little at the base, but without any angles, fig. 16.

A heart-shaped Leaf (*Cordatum*) when they are ovate and hollowed a little at the base, but without any angles, fig. 17.

A moon-shaped Leaf (*Lunulatum*) is a roundish Leaf hollowed at the base, with two curvilinear angles in form of sickles, fig. 18.

An arrow-shaped Leaf (*Sagittatum*) is one which is triangular, and hollowed at the base for the insertion of the foot-stalk, fig. 19.

A heart arrow-shaped Leaf (*Cordatum-sagittatum*) is like the former, but the sides of it are convex, fig. 20.

A spear-pointed Leaf (*Hastatum*) is of a triangular form, the sides and base of which are hollowed, and the angles spreading so as to resemble a Leaf composed of three parts, fig. 21.

A fiddle-shaped Leaf (*Panduræ forme*) is oblong, larger at both ends than in the middle, the two sides being compressed like the body of a violin, fig. 22.

A cleft or divided Leaf (*Fissum*) is divided by linear sinuations and strait margins; from the number of the divisions they are termed a two, three, or many pointed leaf, fig. 23.

A lobated Leaf (*Lobatum*) is one which is divided almost to the midrib, into parts which stand distant from each other, and have convex margins according to the number of these parts; it is called bilobed, trilobed, or quadrilobed, &c. fig. 24.

A handed Leaf (*Palmatum*) is one which is divided into several longitudinal segments down to the base, where they are united, and resemble an open hand, fig. 25.

A wing-pointed Leaf (*Pinnatifidum*) is one which is transversely divided into oblong horizontal divisions, fig. 26.

A lyre-shaped Leaf (*Lyratum*) is one which is divided into transverse segments, the upper ones being larger than the lower, which are farther asunder, fig. 27.

A lacinated or jagged Leaf (*Laciniatum*) is one whose sides are variously divided into jags, which are again divided without any order, fig. 28.

A sinuated Leaf (*Sinuatum*) is one which has many sinuations on its sides, but is not indented or notched on its edges, fig. 29.

An indented sinuated Leaf (*Dentato-sinuatum*) is one like the former, but the side lobes are of a linear figure.

A divided Leaf (*Partitum*) is one which is divided into many parts to the base, so as to appear like many Leaves till closely examined. These are called bipartite, tripartite, &c. according to the number of parts, fig. 30.

An entire Leaf (*Integrum*) is one that is undivided, and has smooth edges.

L E A

Apex tip, is the extremity in which the Leaf terminates; Leaves in respect to these are termed,

A truncated Leaf (*Truncatum*) is one whose summit seems as though it were cut off by a strait line, in a transverse direction.

A bitten Leaf (*Præmorsum*) is one which is terminated by very blunt unequal cuts, fig. 31.

A blunt Leaf (*Retusum*) is one whose extremity is terminated by an obtuse sinus, fig. 32.

A nicked Leaf (*Emarginatum*) is one whose extremity is a little notched, fig. 33.

An obtuse Leaf (*Obtusum*) is one whose point is terminated bluntly, or by a segment of a circle, fig. 34.

A sharp Leaf (*Acutum*) is one whose point is terminated in an acute angle, fig. 35.

An acuminate Leaf (*Acuminatum*) is one which is terminated by an awl-shaped point, fig. 36.

A pointed obtuse Leaf (*Obtusum acuminatum*) is one whose upper part is rounded, but draws to an acute point, fig. 37.

A clasper Leaf (*Cirrhosum*) is one which terminates with a tendril, fig. 38. as in *Gloriosa*, *Flagellaria*, &c.

The margin of a Leaf is the outermost boundary of its sides, exclusive of its disk or middle, so in respect to their margin are,

A spinous Leaf (*Spinosum*) is one whose edge or border ends with hard stiff prickles, fig. 39.

An indented Leaf (*Dentatum*) is one whose edge has horizontal points of the same consistence with the Leaf, but are separated from each other, fig. 40.

A sawed Leaf (*Serratum*) is one whose edges are sharply notched like the teeth of a saw, which make acute angles bending toward the top, fig. 41.

A backward sawed Leaf (*Retrorso-serratum*) is one whose serratures or teeth, are bent toward the base of the Leaf.

A double sawed Leaf (*Duplicato-serratum*) is one whose edges are sawed with larger teeth, and the edges of these are again sawed in the same manner.

A notched Leaf (*Crenatum*) is one whose edges are indented with angles, which neither turn toward the point nor base. When these indentings terminate obtusely, it is called obtuse crenated; when acutely, acute crenated; when the indentures are again indented, it is called double crenated (*Duplicato-crenatum*), fig. 42.

A bowed or serpentine Leaf (*Repandum*) is one whose margin has several obtuse sinuses which are inscribed with the segments of circles, fig. 43.

A cartilaginous or gristly Leaf (*Cartilagineum*) is one whose edge is furnished with a firm cartilage of a different substance with the Leaf, fig. 44.

A ciliated Leaf (*Ciliatum*) is one whose edge is set with parallel hairs, so as to resemble the hairs of the eye-lid, fig. 45.

A torn Leaf (*Laceratum*) is one whose edges are cut into segments of irregular shapes.

A gnawed Leaf (*Erosum*) is one which is sinuated, and the sinuses have their edges again indented with small obtuse sinuations, fig. 46.

A very entire Leaf (*Integerrimum*) is one whose margin is entirely free of all notches or indentures.

The surface (*Superficies*) is the outside, or what covers the disk of the Leaf, and respects both the upper and under surface, so are termed,

A viscous Leaf (*Viscidum*) has its superficies covered with a clammy moisture which is not fluid, but sticky.

A downy Leaf (*Tomentosum*) is one whose surface is covered with a nap of interwoven hairs so short and fine, that the eye does not distinguish them singly, though the Leaf is evidently downy both to the sight and touch, fig. 47.

A woolly Leaf (*Lanatum*) is one whose surface is covered with a kind of woolly substance, like a spider's web, as in *Salvia*, *Sideritis*, &c.

A hairy Leaf (*Pilosum*) has its surface furnished with long distinct hairs, fig. 48.

A rough or stinging Leaf (*Hispidum*) is one whose surface is covered with rigid hairs, which either sting or prick on being touched, fig. 49.

L E A

A rough Leaf (*Scabrum*) is one whose surface has on it several little irregular prominences.

A prickly Leaf (*Aculeatum*) is one whose surface is covered with strong sharp points or thorns, which adhere lightly to the surface.

A streaked or channelled Leaf (*Striatum*) is when its surface has a number of parallel longitudinal furrows.

A pimpled Leaf (*Papillosum*) is one whose surface has many little roundish protuberances like nipples or bladders, fig. 50.

A punctuated Leaf (*Punctatum*) is one whose surface has many hollow points dispersed over it.

A bright or splendent Leaf (*Nitidum*) is one whose surface is smooth and shining, as if polished by art.

A plaited Leaf (*Plicatum*) is one which has several angular risings and hollows towards its borders, as if folded up, as in *Alchimilla*, fig. 51.

A waved Leaf (*Undulatum*) is one whose surface toward the edges rises and falls convexly like the waves of the sea.

A curled Leaf (*Crispum*) is when the circumference of the Leaf grows larger than the disk will admit, so that the whole surface is raised in waves, fig. 52.

A rough leaf (*Rugosum*) is one whose veins are contracted and sunk below the disk, and the intermediate fleshy parts rise in irregular forms, so as to appear rough, fig. 53.

A hollow or concave Leaf (*Concavum*) is one whose margin contracts, so is less than the middle, and is sunk down or hollowed.

A veined Leaf (*Venosum*) is one whose veins are branched, and appear to the naked eye.

A convex Leaf (*Convexum*) is one whose middle rises into a protuberant form.

A nervous Leaf (*Nervosum*) is when the veins are extended lengthways from the base toward the summit without branching, fig. 54.

A coloured Leaf (*Coloratum*) is one which has other colours than green.

A smooth Leaf (*Glabrum*) is one whose surface is smooth, without any inequalities.

The substance of a Leaf respects the conditions of its sides, in this respect Leaves are,

A taper Leaf (*Teres*) is one of a thick substance, and for the most part of a cylindrical form.

A half taper Leaf (*Semicylindraceum*) is one which is of a cylindrical form, flattened on one side.

A hollow Leaf (*Tubulosum*) is one which is hollow like a pipe, as those of the Onion.

A fleshy Leaf (*Carnosum*) is one that is succulent or full of pulp.

A compressed Leaf (*Compressum*) is one whose marginal sides are pressed, so that the substance of the Leaf is larger than the disk.

A plane Leaf (*Planum*) is one whose surfaces are every where parallel.

A gibbous Leaf (*Gibbum*) is one which is convex on both sides, the middle being fuller of pulp.

A depressed Leaf (*Depressum*) is one whose disk is more depressed than the sides.

A guttered Leaf (*Canaliculatum*) is one which has a longitudinal deep furrow running through the middle of the Leaf, and is almost cylindrical, fig. 55.

A double-faced Leaf (*Ancipites*) is one whose disk is convex, and has two prominent longitudinal angles.

A sword-shaped Leaf (*Ensisforme*) is one with thin edges, with a prominent rib running from the base to the point in the middle.

A faulchion or scymiter-shaped Leaf (*Acinaciforme*) is one which is fleshy and compressed, with one of its edges convex and narrow, the other thick and strait, fig. 56.

An ax-shaped Leaf (*Dolabriforme*) is one which is roundish, obtuse, and compressed, gibbous on the outside, the inside sharp-edged and taper below, fig. 57.

A tongue-shaped Leaf (*Linguiforme*) is linear, fleshy, and obtuse, convex on the under side, and has often cartilaginous edges, fig. 58.

A two-

LEA

A two-edged Leaf (*Anceps*) is one which has two prominent angles, running lengthways on a convex disk. A three-cornered Leaf (*Triquetrum*) has three longitudinal plain sides like an awl-shaped Leaf.

A three-edged Leaf (*Trigonal*) is much like the former, but in this the ribs are sharp and membranaceous, the surface of the Leaf being channelled. When a Leaf has four or five angles, it is called tetragonal and pentagonal, &c.

A furrowed Leaf (*Sulcatum*) is one that has several ridges running lengthways, which have obtuse sinus, fig. 59.

A keel-shaped Leaf (*Carinatum*) is one that has the under part of the disk prominent the whole length, and the upper concave like the keel of a boat.

A membranaceous Leaf (*Membranaceum*) is one wholly composed of membranes, without any apparent pulp between.

A compound Leaf (*Compositum*) in general means one, which is formed of several small Leaves standing upon one foot-stalk, but these Leaves are divisible again to the structure and position of the small Leaves.

1st, Into such as are properly and distinctly called compound Leaves; 2dly, the decompound; 3dly, the supradecompound, of each of these in its place.

In describing these kinds of Leaves, the whole Leaf which is the result of the combination, is considered as one Leaf, called (*Folium*) and the small leaves which together compose it (*Folioli*) or lobes.

A simple compound Leaf, is one whose simple foot-stalk bears more than one Leaf.

A jointed one (*Articulatum*) is when one Leaf grows out of the point of another, fig. 60.

A fingered Leaf (*Digitatum*) is one which is composed of several small Leaves joining to one foot-stalk at their base, spreading open like the fingers of a hand, fig. 61.

A two-lobed Leaf (*Binatum*) is one with two small Leaves on one foot-stalk, fig. 62.

A three-lobed Leaf (*Ternatum*) is one with three small leaves, which is frequently called a trifoliate Leaf, fig. 63.

A cinquefoil Leaf (*Quinatum*) has five small Leaves on the same foot-stalk.

A winged Leaf (*Pinnatum*) is one which has many small Leaves, ranged on each side a single foot-stalk like wings; of these there are several kinds.

An unequal winged Leaf (*Pinnatum cum impare*) is a winged Leaf, terminated by an odd lobe or (*Folioli*) fig. 64.

A clasper-winged Leaf (*Pinnatum cum cirrho*) is a winged Leaf ending with a tendril or clasper, fig. 65.

An abrupt-winged Leaf (*Abruptum*) is a winged Leaf not terminated by an odd lobe or clasper, fig. 66.

An opposite-winged Leaf (*Opposite pinnatum*) is when the small Leaves or lobes are placed opposite on the midrib.

An alternate-winged Leaf (*Alternatim pinnatum*) is when the small Leaves stand alternate.

An interrupted-winged Leaf (*Interruptè pinnatum*) is when there are smaller lobes intermixed with larger upon the same midrib, fig. 67.

A jointed-winged Leaf (*Articulatè pinnatum*) is when the common foot-stalk is jointed, fig. 68.

A running-winged Leaf (*Decursivè pinnatum*) is one whose small Leaves run along the foot-stalk from one to another, fig. 69.

A conjugated Leaf (*Conjugatum*) is one which has but two small Leaves on the same foot-stalk.

We next proceed to the decompounded Leaves.

A decompounded Leaf (*Decompositum*) is one whose foot-stalk is once divided, and joins together many small Leaves.

A double conjugated Leaf (*Bigeminatum*) is one whose foot-stalk divides in forks, and connects four small Leaves on the top, or it is composed of two conjugations.

A double trifoliate Leaf (*Biternatum*) is one whose foot-stalk is divided, and each division sustains three small Leaves, fig. 70.

LEA

A double-winged Leaf (*Bipinnatum*) is one whose foot-stalk is divided, and these divisions have small Leaves ranged on their side like wings, fig. 71.

A foot-shaped or branched Leaf (*Pedatum*) is one whose foot-stalk is divided, and has some small Leaves placed on the inner side, as in *Passiflora* and *Arum*, fig. 72.

A greater compounded Leaf (*Supra decompositum*) is one whose foot-stalk is many times divided, and each division is garnished with small Leaves.

A triternate Leaf (*Triternatum*) is one whose foot-stalk connects three double trifoliate Leaves.

A triple-winged Leaf (*Tripinnatum*) is one composed of several double-winged Leaves; if these are terminated by two small Leaves, they are said to be abrupt, fig. 73. but when they are terminated by an odd one, they are called an irregular, triple, winged Leaf, fig. 74.

We next come to consider the distinctions of Leaves from their place, position, insertion, or their direction, when joined to the other parts of plants.

A seed Leaf (*Seminale*) is the first Leaf of the plant, and is what former writers called cotyledones; these are different in form and substance from the other Leaves, fig. 75.

A bottom Leaf (*Radical*) is one whose foot-stalk rises immediately from the root.

An upper or stalk Leaf (*Caulinum*) is one which grows from the stalk of the plant, fig. 76.

An axillary Leaf (*Axillare*) is one which grows from the insertions of the branches, fig. 77.

A flower Leaf (*Florale*) is one that is inserted near the flower, and never appears but with it, fig. 78.

A starry Leaf (*Stellate*) fig. 79. or whorled Leaf (*Verticillata*) is when several Leaves are disposed in whorls round the stalk, fig. 80.

Opposite Leaves (*Opposita*) are when those upon the stalks stand by pairs on each side, fig. 81.

Alternate Leaves (*Alterna*) are when they stand alternate above each other, fig. 82.

Sparsed Leaves (*Sparsa*) are such as stand without order over the whole plant.

Cluster Leaves (*Conferta*) are such as come out from the side of the branches in clusters, and are so close to one another, that it is not easy to discover their exact situation, fig. 83.

Imbricated Leaves (*Imbricata*) are such as are placed over each other like tiles on a house, or the scales of fishes, fig. 84.

Fasciculated Leaves (*Fasciculata*) are such as grow in clusters from the same point, fig. 85.

Disticha is when the Leaves are ranged along only upon two sides of the branches, as in the Fir-tree.

A target or shield-shaped Leaf (*Peltatum*) is one whose foot-stalk is fixed to the disk, and not to the base or edge of the Leaf, fig. 86.

Petiolum is when the foot-stalk is inserted to the base of the margin, fig. 87.

Sessile is when the Leaf sits close to the stalk or branch, and has no foot-stalk, fig. 88.

A running Leaf (*Decurrens*) is when the Leaf adheres to the stalk or branch, and is extended along the stalk from the base, so as to form a leafy border on each side the stalk, fig. 89.

Amplexicaule is when the base of the Leaf environs or embraces the sides of the stalk entirely, fig. 90.

Semiamplexicaule, is when the base of the Leaf reach but half round the stalk.

A perfoliate Leaf (*Perfoliatum*) is one which is perforated by the stalk or branch, which do not touch the margin, fig. 91.

Connatum, is when the two opposite Leaves cohere at their base, so as to form one body embracing the stalk, fig. 92.

Vaginans, is when the base of the Leaf forms a kind of cylinder, embracing the stalk like a sheath, as in Corn, Grass, fig. 93.

The direction of Leaves.

An adverse Leaf (*Adversum*) is one whose sides respect the meridian and not the heavens, as the Ginger, &c.

An oblique Leaf (*Obliquum*) is when the base of the Leaf regards the sky, and the summit the horizon.

An inflexed or incurved Leaf (*Inflexum*) is one which grows in form of a bow, turning its point toward the stalk again, fig. 94.

Alapressum, is when the disk of the Leaf approaches near the stalk.

An erect Leaf (*Erectum*) is one so situated as to make a very acute angle with the stalk; fig. 95.

Patens, is when the Leaf does not make so acute an angle with the stalk as the former, and yet does not stand horizontal, fig. 96.

An horizontal Leaf (*Horizontale*) is one which stands perfectly at right angles with the stalk, fig. 97.

A reclined Leaf (*Reclinatum*) is one whose summit is lower than the base, fig. 98.

A rolled Leaf (*Revolutum*) is one whose upper part is rolled downward, fig. 99.

A dependent Leaf (*Dependens*) is one whose summits point to the earth.

A rooting Leaf (*Radicans*) is one which puts out roots.

A floating Leaf (*Natans*) is one which floats on the surface of the water, as the Water Lily, &c.

Demersum, is used to express a Leaf sunk below the surface of the water.

Having explained the several forms of Leaves, by which botanists distinguish them, and also their position, both in regard to the other parts of the tree, or plant, and that of the earth, we shall next proceed to their structure and uses; for these were not designed by the wise Creator only for ornament, but they are of more important use in vegetation, and are as variously constructed in their several parts, as their several uses for which they are designed.

Some plants have very thick fleshy Leaves, whose pulpy substance is always moist; these are such plants as naturally grow upon dry barren rocky places, and for the most part are natives of warm countries; and as they perspire very little in comparison of most other plants, they are adapted to grow in such places where they can receive very little nourishment from the earth. Most of the Leaves of these plants have a thin compact skin over their surface, with very small minute pores, whereby the descending moisture is thrown off, which, if admitted into the substance of the Leaves, or stalks, would in a very short time cause a mortification, and destroy the plant.

The Leaves of all those trees and shrubs which continue their verdure all the year, have also a thin compact skin or cover over their surfaces, as is easily discovered by macerating them in water, in order to separate the parenchyma from the vessels of the leaves, which cannot be effected in any of these Evergreens, till the thin parchment-like cover is taken off; these trees and shrubs are found, by experiment, to imbibe and perspire but little in the same space of time, when compared with the deciduous trees and shrubs; and it is principally owing to this close covering, as also to the small proportion of moisture contained in their vessels, that they retain their verdure, and continue through the winter on the trees. The nutritive juices of these plants always abound more or less with an oily or terebinthinous quality, which secures them from the injury of frost, so that many of these evergreen trees are adapted to grow in the coldest parts of the habitable world.

In all the Leaves of trees and plants which I have examined, there are two orders of veins or nerves, one belonging to each surface; and I have generally observed, that the lower lamina or under side of the Leaf, had the ramifications larger, and were capable of admitting a liquid to pass through them, which those of the upper surface would not; these two orders of veins are inosculated at several places, but not so closely connected, but that they may be easily separated, after they have been macerated in water a proper time, for some Leaves require a much longer time than others, to render the parenchyma soft enough to separate easily from the veins without tearing them.

These two laminæ, or orders of veins, are supposed to be destined for different purposes; the upper lamina is thought to be air-vessels; or trachæ, through which the perspiring matter is protruded, and by which the air is inspired; that these are pores through which that substance passes, which is thrown out of the plants, is pretty evident; for the clammy substance which is commonly called honey-dew, is always found sticking to the upper surface of Leaves, from whence many have supposed that this substance fell from above, and lodged upon the Leaves in the night. This is the Manna which is collected from Ash-trees in Calabria, and from the Albagi in Persia, &c. and is no other than the nutritive juices, or a substance separated from that, which issues from the pores of the Leaves, and is concreted on the surface of the Leaves by the cold air; but whenever this is found in quantity upon the Leaves, it is a sure sign of a diseased plant.

The lower lamina of veins are supposed to be destined for another purpose, which is that of receiving, preparing, and conveying the moisture imbibed from the rising vapours of the earth, by which trees and plants are greatly nourished; and for this use we see how differently the two surfaces are formed; the upper one is commonly smooth and lucid, and the under is frequently covered with hairs, or a soft down, the better to stop and detain the rising vapours, and transmit them to the inner vessels; and where the structure of the Leaves are different, it is found by experience, that their functions alter; for those Leaves, whose upper surfaces are garnished with down or hairs, are found to be the receivers and conveyers of the moisture, and not the under ones, as in the other plants.

If the surfaces of these Leaves are altered, by reversing the branches on which they grow, the plants are stopped in their growth, until the foot-stalks are turned, and the Leaves recover their former position. This shews how necessary it is to support all those weak shoots of plants, which are naturally disposed for upright growth, and that either twine about the neighbouring trees for support, or that put out claspers, by which they take hold of whatever trees or plants grow near them, and are thereby supported; and, on the contrary, how absurd is that practice of tying up the shoots of those plants which are naturally disposed to trail upon the ground; for, in both these cases, nature is reversed, and consequently the growth of both sorts of plants is greatly retarded.

This is one of the great functions for which the Leaves of trees and plants are designed; but, besides this, there are others of equal importance to the well-being of plants and fruits; the first is that of the foot-stalks of Leaves nourishing and preparing the buds of the future shoots, which are always formed at the base of these foot-stalks, and during the continuance of the Leaves in perfect health, these buds increase in their magnitude, and, in the deciduous trees, are brought to maturity before the foot-stalks separate from the buds in autumn; but if by accident the Leaves are blighted, or if the entire surface of the Leaves are cut off, and the foot-stalks are left remaining, yet the buds will decay, or not arrive to their proper size, for want of that nourishment which is conveyed to them from the Leaves; so that whenever trees are divested of their Leaves, or those Leaves are cut, or otherwise impaired, though it may in either case happen when the buds may be nearly formed; yet if it is before the foot-stalks separate naturally from the branches, the future shoots will be weakened in proportion to the time when this is done; therefore, as from all the experiments which have been made in order to know how serviceable the Leaves of trees and plants are to their well-being, it has been found, that where the plants have been divested of their Leaves, or their Leaves have been eaten, or cut, during their growth, the plants have been remarkably weakened thereby. This should teach us not to pull, or cut off the Leaves of trees, or plants, on any account, while they retain their verdure or are in health.

health. As also how absurd that common practice is, of feeding down Wheat in the winter and spring with sheep; for by so doing, the stalks are rendered very weak, and the ears are in proportion shorter; nor are the grains of Corn so plump and well nourished, as that which is not fed down upon the same ground: this is a fact which I can assert from many years experience; for when Corn or Grass is fed down close to the root, the succeeding blades will be much finer than if the first Leaves had been left remaining; which is evident from all sheep pastures, where the Grass is much finer and shorter than in other places; as also upon lawns and bowling-greens, where the Grass is often mowed, the blades will be rendered finer in proportion to the frequency of mowing it, yet the species of Grass is the same with that on the richest pastures; so that although this may be a desirable thing for lawns, &c. in gardens, yet where regard is had to the produce, this should be avoided.

Besides these, there are other uses for which Leaves are designed, one of which is that of shading the buds for the future shoots from the sun, which would exhale and dry up all their moisture, as also the shading of the young fruit, which is absolutely necessary during the time of their growth; for I have suspended the Leaves of trees which were growing against walls, so as to expose the fruit to the sun, and not taken any of them off the branches, yet I have always found those fruits so exposed, have been greatly stunted in their growth, and have never arrived to near the size of others above and below them on the same branches, nor were they so well tasted, or replete with juice.

In making this experiment, I was as careful as possible not to reverse the surfaces of the Leaves, having been thoroughly convinced, from many repeated experiments, how prejudicial that is to all plants; but notwithstanding this precaution, the event was as before-mentioned.

Another principal use of the Leaves is to throw off by transpiration, what is unnecessary for the growth of the plants, answering to the discharge made by sweat in animal bodies; and as plants receive and transpire much more, in equal time than large animals, so it appears how necessary the Leaves are to preserve the plants in perfect health; for it has been found by the most exact calculations, made from repeated experiments, that a plant of the Sun-flower receives and perspires, in twenty-four hours, seventeen times more than a man.

As naturalists have generally ascribed a four-fold use to Leaves, I shall beg leave to mention them here, and then shall give an account of the most accurate experiments which have been made to ascertain the truth of their hypotheses.

1. Chiefly, that they do in the spring time receive the crude humours into themselves, divide them very minutely, and move them strongly in the utricles, and perhaps draw in from the air what is necessary, though unknown to us, and carry back great plenty of elaborate juice to the plant.

2. That there may be a transpiration of what is unprofitable, answering to the discharge made by sweat; for sometimes those excretory vessels of the Leaves are so overcharged by the great plenty of distending humour [juice,] that they burst in the middle, and let go the more subtle parts; nor is it seldom, that, in a hot season, great plenty of juices are this way discharged and imbibed. Thus Manna is found to exude [sweat forth] from the Leaves of certain trees, if a cold night should follow a hot day; and the same thing frequently happens in divers other plants and trees, as we learn from the bees flying to the Lime-tree, that they may gather that gumous substance from their Leaves; and it is from the surfaces of the Leaves, as well as from the flowers, those animals collect their honey; but if the heat should be less, all the superfluous humours, except those which, perhaps, are transmitted by insensible transpiration thro'

the arterial vessels, exhaling naturally, are seen to return into the trunk.

3. That the bibulous vessels, dried by the diurnal heat, and for this reason to be compared to veins, may imbibe, in the night-time especially, those watery parts, which, among others, lie hid in the air under the form of a very thin dew, and so make amends for the loss made by the arteries, by the new moisture received.

4. Lastly, the Leaf serves chiefly for this purpose, that it may keep and nourish the eye, or gem, until the gem, by degrees growing out to a greater bulk, presses together the vessels of the foot-stalk, from whence the humour is by little and little stopped in the Leaf, till it cannot any more return to the foot-stalk; which, by the ceasing of the afflux and reflux of the nutritive juice, grows putrid, whence a consumption being caused, the Leaf dies, and falls off, which is the chief cause of the falling of the Leaves in autumn.

The Rev. Dr. Hales, in his excellent Treatise of Vegetable Statics, speaking of the perspiration of plants, gives an account of the following experiments, viz.

That in July or August he cut off several branches of Apple-trees, Cherry-trees, Pear-trees, and Apricot-trees, two of a sort; they were of several sizes, from three to six feet long, with proportional lateral branches, and the transverse cut of the largest part of the stems was about an inch diameter.

That he stripped off the Leaves of one bough of each sort, and then set their stems in several glasses, pouring in known quantities of water.

The boughs with Leaves on them imbibed some fifteen ounces, some twenty, twenty-five, or thirty, in twelve hours day, more or less, in proportion to the quantity of Leaves they had, and when he weighed them at night, they were lighter than in the morning. While those without Leaves imbibed but one ounce, and were heavier in the evening than in the morning, they having perspired little.

The quantity imbibed by those with Leaves decreased very much every day, the sap-vessels being probably shrunk at the transverse cut, and too much saturate with water, to let any more pass, so that usually in four or five days the Leaves faded and withered much.

He adds, that he repeated the same experiments with Elm branches, Oak, Osier, Willow, Sallow, Aspen, Currant, Gooseberry, and Filbert branches, but none of these imbibed so much as the foregoing, and several sorts of Evergreens very much less.

He adds also another experiment: That on the 15th of August, he cut off a large Pippin with two inches stem, and its twelve adjoining Leaves: that he set the stem in a little phial of water, which imbibed and perspired in three days one third of an ounce.

And that at the same time he cut off from the same tree another bearing twig of the same length, with twelve Leaves, no Apple on it, which imbibed in the same three days near three-fourths of an ounce.

That about the same time, he set in a phial of water a short stem of the same tree, with two large Apples on it, without leaves, and they imbibed near three-fourths of an ounce in two days.

So in this experiment, the Apples and Leaves imbibed four-fifths of an ounce, the Leaves alone near three-fifths, but the two large Apples imbibed and perspired but one third part so much as the twelve Leaves, then the one Apple imbibed the one-sixth part of what was imbibed by the twelve Leaves; therefore two Leaves imbibe and perspire as much as one Apple; whence their perspirations seem to be proportionable to their surfaces, the surface of the Apple being nearly equal to the sum of the upper and under surfaces of the two Leaves.

Whence it is probable that the use of these Leaves (which are placed just where the fruit joins to the tree) is to bring nourishment to the fruit.

And

LEA

And accordingly he observes, that the Leaves next adjoining to the blossoms are in the spring very much expanded, when the other Leaves on barren shoots are but beginning to shoot, and that all Peach Leaves are very large before the blossom goes off.

And that, in Apples and Pears, the Leaves are one-third or half grown, before the blossom opens, so provident is nature in making timely provision for the nourishing the yet embryo fruit.

He also adds another experiment: he stripped the Leaves of an Apple-tree branch, and then fixed the great end of the stem in the gage, it raised the mercury $2 + \frac{1}{2}$ inches, but it soon subsided, for want of the plentiful perspiration of the Leaves, so that the air came in almost as fast as the branch imbibed water.

And as a farther proof of the influence of the Leaves in raising the sap, he also made the following experiment.

On the sixth of August, he cut off a large Russet Pippin, with a stalk $1 + \frac{1}{2}$ inch long, and twelve adjoining Leaves growing to it.

He cemented the stalk fast in the upper end of a tube, which tube was six inches long, and one-fourth diameter; as the stalk imbibed the water, it raised the mercury four inches high.

That he fixed another Apple of the same size in the same manner, but first pulled off the Leaves, and it raised the mercury but one inch; that in the same manner he fixed a like-bearing twig, with twelve Leaves on it, but no Apple, and it raised the mercury three inches.

He then took a like-bearing twig, without either Leaves or Apple, and it raised the mercury one-fourth of an inch.

So a twig, with an Apple and Leaves, raised the mercury four inches; one with Leaves, only three inches; one with an Apple without Leaves, only one inch.

A Quince, which had two Leaves just at the twig's insertion, raised the mercury $2 + \frac{1}{4}$ inches, and held it up a considerable time.

A sprig of Mint, fixed in the same manner, raised the mercury $3 + \frac{1}{2}$ inches, = to 4 feet 5 inches height of water.

These, and many more experiments of the Rev. Dr. Hales, that curious enquirer into the causes, state, and progress of vegetation, evidently shew the great perspiration of the Leaves of plants, and their great use in raising the sap, and other functions of vegetable nature; to whose excellent treatise before-mentioned, I refer the curious enquirer.

I shall add, That nature has directed us as to the true distance we ought to train the branches of trees against walls or espaliers, which should always be in proportion to the size of their Leaves; for if we regard her progress in the great varieties of trees, which are within our observation, we shall always find their branches grow distant from each other in proportion to the breadth of their Leaves; and it was upon this account that the Romans so much admired the Platanus, because the Leaves, being large, afforded them a kindly shade in summer, but in winter, when they are destitute of Leaves, their branches growing at a great distance, easily admitted the beams of the sun.

I shall next beg leave to mention a few, out of the many experiments which have been made by Mons. Bonnet, of Geneva, to prove that most Leaves imbibe the moisture of the air on their under surface, and not from their upper: they are as follow:

He gathered the Leaves of sixteen sorts of herbaceous plants when fully grown; of each he put several Leaves upon the surface of water in glass vases, some were posited with their upper surface, and others with their under surface upon the water; these were adjusted exactly to the surface of the water, with great care not to let any moisture reach their opposite surfaces, and the same care was taken to prevent their foot-stalks from receiving any moisture. The glasses in which these Leaves were thus placed, were kept in a

LEA

closet, where the air was very temperate; and as the water in the glasses evaporated, there was from time to time a supply of fresh, which was added with a syringe, so that the Leaves were not disturbed. The Leaves were taken from the following plants; the Plantain, the Mullein, the Wake Robin, the great Mallow, the Nettle, the Marvel of Peru, the Kidney-bean, the Sun-flower, the Cabbage, the Balm, the Cock's-comb, the purple-leaved Amaranth, Spinach, and the smaller Mallow.

Six of these sorts he found continued green a long time, and these were with different surfaces upon the water; they were of the following sorts, the Wake Robin, the Kidney-bean, the Sun-flower, the Cabbage, the Spinach, and small Mallow; among the others the following sorts were found to draw the moisture better with their upper surface than their under, the Plantain, the Mullein, the great Mallow, the Nettle, the Cock's-comb, and the purple Amaranth.

The Leaves of the Nettle whose under surface was upon the water, were decayed in three weeks, whereas those whose upper surface was next the water continued two months.

The Leaves of Mullein, whose under surface was next the water, did not continue fresh more than five or six days, but those whose upper surface was next the water lasted five weeks.

The Leaves of the purple Amaranth, whose upper surface was next the water, continued fresh three months, whereas those whose under surface was next the water, were decayed in a week.

The Leaves of the Marvel of Peru and the Balm, appeared to have the advantage, whose under surfaces were next the water.

The Leaves of Wake Robin and of the Cock's-comb, whose foot-stalks only were put into the water, continued fresh a longer time than those which were placed with either surface next the water.

The Leaves of the Great Mallow, the Nettle, the Sun-flower, the Marvel of Peru, and Spinach, whose foot-stalks were plunged into the water, continued fresh a shorter time than those which had either of their surfaces next the water.

The Leaves of the Mullein, of Plantain, and Amaranth, which received the water at their foot-stalk, continued fresh much longer than those, whose under surface was next the water.

It is not difficult to explain the reason of this fact, for the orifices of the sap-vessels in the foot-stalk, are much larger than those of either surface, so that the moisture insinuates in greater quantities, and with more ease, the first than by the second way.

After this the same gentleman made experiments on the Leaves of sixteen sorts of trees and shrubs of the following sorts, the Lilac, the Pear-tree, the Vine, the Aspen, the Laurel, the Cherry-tree, the Plumb-tree, the Horse Chestnut, the White Mulberry, the Lime-tree, the Poplar, the Apricot, the Walnut, the Filbert, the Oak, and the Creeper.

Among these species, he found that the Lilac and the Aspen imbibed the moisture on their upper surface, equally with the under surface; but in all the other sorts, the under surface imbibed it in much greater quantities than the opposite. The difference was very remarkable in the Leaves of the White Mulberry, for those whose upper surface was laid upon the water, faded in five days, whereas the other whose under surface was next the water, preserved their verdure near six months.

The Vine, the Poplar, and Walnut-tree are very remarkable instances, how little disposed the upper surfaces of the Leaves of ligneous plants are to imbibe the moisture; for those of these three sorts, whose upper surfaces were applied to the water, decayed almost as soon as those which had no nourishment.

In all the experiments made by this curious gentleman upon the various Leaves of trees and herbs, it is remarkable, that all those Leaves which imbibed the moisture by their upper surface, were such as had that

LEA

that surface covered with either hairs or down; and on the contrary, where the under surface was garnished with either hairs or down, the moisture was imbibed by that surface. He likewise mentions many experiments made by himself, and also by Monsi. du Hamel de Monceau, of the Royal Academy of Sciences at Paris, in rubbing the Leaves over with varnish, oil, wax, and honey, to see the effect of these upon various Leaves, some of which were rubbed over on both surfaces, others only upon one; some only a part of the surface, others the edges of the Leaves were rubbed over, and in some only the foot-stalks of the Leaves were rubbed with these. They likewise anointed the trunks of some trees and shrubs, and left the Leaves and branches in their natural state.

The result of these experiments was, that where the Leaves were anointed on both surfaces with varnish, they decayed presently; and where they were anointed with the other things, in proportion as those were most penetrating, so the Leaves continued a shorter time than the others; and where one surface only was anointed, they continued much longer than those which were anointed on both; and where the pedicle only was anointed, they continued still longer; but the anointing of the trunks, made no sensible alteration, excepting in very hot weather, when they both imagine, that the anointing them was of service, by hindering the too great transpiration which might weaken the trees; for they observed, that those trees which were varnished, suffered less from the violent heat, than the trees which were left in their natural state.

Monsi. Bonnet also observed, that those Leaves which were varnished, the tender parts of the Leaves were destroyed by it, and the tough fibres only were left remaining.

As it would swell this work much beyond its intended bulk, were I to mention more of these curious experiments, I shall refer the curious to his book, where they will find a great number of the most accurate and well conducted experiments related, to ascertain the uses of the Leaves of plants in vegetation.

The before-mentioned Rev. Dr. Hales, in his Treatise of Vegetation, says, it is plain from many experiments and observations he had before mentioned, that Leaves are very serviceable in this work of vegetation, by being instrumental in bringing nourishment from the lower parts, within the reach of the attraction of the growing fruit, which, like young animals, is furnished with proper instruments to suck it thence; but the Leaves seem also designed for many other noble and important services; for nature admirably adapts her instruments, so as to be at the same time serviceable to many good purposes.

Thus the Leaves, in which are many excretory ducts in vegetables, separate and carry off the redundant watery fluid, which, by being long detained, would turn rancid, and prejudicial to the plant, leaving the more nutritive parts to coalesce; part of which nourishment, we have good reason to think, is conveyed into vegetables through the Leaves, which plentifully imbibe the dew which contain salt, sulphur, &c.

For the air is full of acid and sulphureous particles, which, when they abound much, do, by the action and reaction between them and the elastic air, cause that sultry heat which usually ends in lightning and thunder; and these new combinations of air, sulphur, and acid spirit, which are constantly forming in the air, are doubtless very serviceable in promoting the work of vegetation; when, being imbibed by the Leaves, they may not improbably be the materials, out of which the more subtle and refined principles of vegetables are formed; for so fine a fluid as the air seems to be a more proper medium, wherein to prepare and combine the more exalted principles of vegetables, than the grosser watery fluid of the sap:

LEO

and for the same reason it is likely that the most refined and active principles of animals are also prepared in the air, and thence conveyed through the lungs into the blood; and that there is plenty of these sulphureo-aereal particles in the Leaves, is evident from the sulphureous exudations that are found in the edges of Leaves, of which bees are observed to make their waxen cells, as well as of the dust of flowers. And that wax abounds with sulphur, is plain from its burning freely, &c.

We may therefore reasonably conclude, that one great use of Leaves is what has been long suspected by many, viz. to perform, in some measure, the same office for the support of the vegetable life, as the lungs of animals do for the support of animal life; plants, very probably, drawing through their Leaves some part of their nourishment from the air.

LEDUM. Raii Syn. 1—142. Lin. Gen. Plant. 483. Marsh Cistus, or wild Rosemary.

The CHARACTERS are,

The flower has a small empalement of one leaf, indented in five parts. It hath five oval, concave, spreading petals, and ten slender stamina the length of the petals, which spread open, terminated by oblong summits, and a roundish germen supporting a slender style, crowned by an obtuse stigma. The germen afterward becomes a roundish capsule with five cells, opening at the base in five parts, and filled with small, narrow, acute-pointed seeds.

This genus of plants is by Dr. Linnæus ranged in the first section of his tenth class, intitled Decandria Monogynia, which includes those plants whose flowers have ten stamina and one style.

We have but one SPECIES of this genus, viz.

LEDUM (Palustre) foliis linearibus subtus hirsutis, floribus corymbosis. Flor. Suec. 341. *Ledum with very narrow leaves, hairy on their under side, and flowers growing in a corymbus.* Rosmarinum sylvestre minus nostras. Park. Hist. 76. *Our small wild Rosemary.*

This plant grows naturally upon mosses and bogs in many parts of Yorkshire, Cheshire, and Lancashire, where it rises with a slender shrubby stalk about two feet high, dividing into many slender branches, which are garnished with narrow leaves not much unlike those of Heath. The flowers are produced in small clusters at the end of the branches, which are shaped like those of the Strawberry-tree, but spread open wider at the top. These are of a reddish colour, and appear in May, and in the natural places of their growth, are succeeded by seed-vessels filled with small seeds, which ripen in the autumn.

It is with great difficulty this plant is kept in a garden, for as it naturally grows upon bogs, so unless the plants have some such soil and a shady situation, they will not thrive. The plants must be procured from the places of their growth, and taken up with good roots, otherwise they will not live. They cannot be propagated in gardens, but in the mosses their roots spread and propagate pretty freely.

LEEKs. See PORRUM.

LEGUMES, or LEGUMENS, are a species of plants which are called pulse, such as Peas, Beans, &c. and are so called, because they may be gathered by the hand without cutting. Mr. Ray reckons all those plants which have a papilionaceous flower, among the Legumes; but the French comprehend most sorts of esculent plants, under this general title of Legumes.

LEGUMINOUS, of or belonging to pulse.

LEMNA. Lin. Gen. 1038. *Lens Palustris, Duck-Meat.* This is a very common plant, growing upon standing waters in most parts of England; where, if it is not disturbed, it will soon cover the whole surface.

LEMON-TREE. See LIMON.

LENS. See ERVUM.

LENTISCUS. See PISTACIA.

LEONTICE. Lin. Gen. Plant. 423. *Leontopetalon.* Tourn. Cor. 49. tab. 484. *Lion's Leaf.*

The

The CHARACTERS are,

The empalement of the flower is made up of six very narrow leaves, which are alternately smaller and drop off. The flower has six oval acute petals, which are twice the length of the empalement, and six nectariums which are fixed by small foot-stalks to the base of the petals. It has six short slender stamina, terminated by erect summits. In the center is placed an oblong oval germen, supporting a short taper style, inserted obliquely to the germen, crowned by a simple stigma. The germen afterward becomes a globular swollen berry a little succulent, with one cell, inclosing two or three globular seeds.

This genus of plants is ranged in the first section of Linnæus's sixth class, which includes those plants whose flowers have six stamina and one style.

The SPECIES are,

1. LEONTICE (*Chrysogonum*) foliis pinnatis, petiolo communi simplici. Hort. Cliff. 122. *Lion's Leaf*, with winged leaves having one common single foot-stalk. *Leontopetalon foliis costæ simplici innascentibus*. Tourn. Cor. 49. *Lion's Leaf with a single foot-stalk to the leaves*.
2. LEONTICE (*Leontopetalum*) foliis decompositis, petiolo communi trifido. Hort. Cliff. 122. *Lion's Leaf with decomposed leaves, and a common trifid foot-stalk*. *Leontopetalon foliis costæ ramosæ innascentibus*. Tourn. Cor. 49. *Lion's Leaf with a branching foot-stalk to the leaves*.

These plants both grow naturally in the islands of the Archipelago, and also in the Corn fields about Aleppo, where they flower soon after Christmas. They have large tuberous roots about the size of those of Cyclamen, covered with a dark brown bark; the leaves arise upon slender foot-stalks immediately from their roots, which grow about six inches high; that of the first sort is single, having many small folioli ranged along the midrib, but the footstalks of the second sort are branched into three smaller; upon each of these are ranged several folioli or small leaves, in the same form as the winged leaves. The flowers sit upon naked foot-stalks, those of the first sort sustain many yellow flowers, but the flowers of the second are smaller and of a paler colour. These in their native country appear soon after Christmas, but in England they do not flower till the beginning of April, and are never succeeded by seeds here.

Both these plants are propagated by seeds, which require to be sown soon after they are ripe, otherwise they seldom succeed; but as they are brought from distant countries, they should be preserved in sand to be sent to England. I received a few of the seeds from the Duke D'Ayen, which were sent him from Aleppo, put up in sand, and these came up better than any of those which came over dry; for of several parcels of these seeds which I have sown of both kinds for three years successively, I had not more than two plants arise.

The plants are very difficult to preserve in England, for the roots will not thrive in pots; and when they are planted in the full ground, the frost frequently destroys them in winter, especially where the roots are young. Of late years the winters have proved so very unfavourable, as to kill all the young roots which I had raised in the Chelsea garden: but before the severe winter in 1740, I had some of the roots which were planted in a south-west border that flowered several years, and without any shelter survived the winters; but although I covered many of those roots which I had lately raised, yet I could not preserve them.

The leaves of these plants decay about Midsummer, and the roots remain in an inactive state till the following spring, at which time the flowers and leaves come up nearly at the same time.

When the seeds are procured from abroad, the best way is to sow them as soon as they arrive, and cover them with glasses in the winter to protect them from frost; and in the spring, when the plants begin to appear, they must have the free air admitted to them at all times when the weather is mild, otherwise they are very subject to draw up tall with weak stems, and

their roots do not increase in their bulk. If the plants are not too close, it will be best to let them remain in the place unremoved till the second year; but where they are too close, part of the roots may be taken up in October, and transplanted close to a warm wall, being very careful not to disturb the roots which are left standing; and in November, before the hard frost sets in, it will be a good way to lay some old tanners bark over the surface of the ground, three or four inches thick, to prevent the frost from penetrating to the roots; but this should be most of it taken off in March, before the roots begin to push out their leaves; and if this is removed in part soon after the hard frost is over in February, and another part three weeks or a month after, it will be better than taking it all off at the same time; and if a thin covering of the tan is left at the last over the surface of the ground, it will prevent the drying winds of the spring from drying the ground, which will be of great service to the roots. These roots should have a dry loose soil, and must be seldom removed; but when that is done, October is the best time, for then the roots are inactive.

LEONTODON. Lin. Gen. Plant. 817. *Dens leonis*. Tourn. Inst. R. H. 468. *Dandelion*; in French, *Dent de Lion*.

There are four or five species of this genus, which grow naturally in the fields either in England or France, so are seldom cultivated in gardens; but as some people in the spring gather the roots out of the fields, and blanch them in their gardens for a salad herb, so I have mentioned the genus, but shall forbear saying any thing more of them, than that they are very bad weeds both in gardens and fields; so should be rooted out before their seeds are ripe, otherwise they will spread to a great distance, as they have down adhering to them, by which they are wafted about by the wind.

LEONTOPodium. See PLANTAGO.

LEONURUS. Tourn. Inst. R. H. 187. tab. 87. *Phlomis*. Lin. Gen. Plant. 642. [*Λιωνύριον*, of *Λίον*, a lion, and *ὄρεα*, a tail, because the crest of this flower seems to resemble the tail of a lion.] *Lion's Tail*.

The CHARACTERS are,

The flower has a tubulous, five-cornered, permanent empalement of one leaf; the flowers have one petal, of the lip or ringent kind; the upper lip is long, cylindrical, hairy, and entire; the lower is short, reflexed, and cut into three parts. It hath four stamina situated under the lower lip, two of which are shorter than the other; these are terminated by oblong compressed summits. In the bottom of the tube are situated four germen supporting a slender style, situated with the stamina, crowned by a bifid acute stigma. The germen afterward become four oblong angular seeds, sitting in the empalement.

This genus of plants is ranged in the second section of Tournefort's fourth class, which includes the herbs with a lip flower of one leaf, whose upper lip is hollowed like a spoon. Dr. Linnæus has joined the species of this genus to the *Phlomis*, and has applied this title to the *Cardiaca*, from which he separates these plants, because they have no punctures on their summits. These he ranges in the first section of his fourteenth class, which includes the plants with a ringent (or grinning) flower, that have two long and two shorter stamina, and naked seeds succeeding, sitting in the empalement.

The CHARACTERS are,

1. LEONURUS (*Africana*) foliis lanceolatis, obtusè serratis. Hort. Cliff. 312. *Lion's Tail with spear-shaped leaves which are bluntly sawed*. *Leonurus perennis Africanus, sideritidis folio, flore Phœnicio majore*. Breyn. Cent. 1. 171. *Perennial African Lion's Tail with an Ironwort leaf, and a larger scarlet flower*.
2. LEONURUS (*Nepetæfolia*) foliis ovatis, calycibus decagonis, septem dentatis, inæqualibus. Hort. Cliff. 312. *Lion's Tail with oval leaves, an empalement having ten corners, and seven unequal indentures*. *Leonurus minor capitis Bonæ Spei, vulgò. Boerh. Ind. alt. 180. Small Lion's Tail of the Cape of Good Hope*.

LEP

The first sort is a native of Ethiopia, but has been long cultivated in the English gardens. This rises with a shrubby stalk seven or eight feet high, sending out several branches from the side, which are four-cornered; these are garnished with oblong narrow leaves, acutely indented on their edges; they are about three inches long, and half an inch broad, hairy on their upper side, and veined on their under, standing opposite. The flowers are produced in whorls round the branches, each of the branches having two or three of these whorls toward their ends, sitting very close to the branches; they are of the lip kind, shaped somewhat like those of the Dead Nettle, but their crests are much longer and covered with short hairs; they are of a golden colour, so make a fine appearance. The flowers commonly appear in October and November, and sometimes continue till the middle of December, but are not succeeded by seeds here.

There is a variety of this sort with variegated leaves, which is by some admired; but as this seldom produces so large whorls of flowers as the plain sort, it is not so generally esteemed.

The second sort is mentioned by several authors as an annual plant; they also suppose it to be a native of America, and believe it was brought from Surinam to Holland; but it is undoubtedly a native of the Cape of Good Hope, from whence I have two or three times received the seeds; and the late Dr. Boerhaave assured me, that he frequently received the seeds from that country, as also a painting of the plant, so that he made no doubt of the plant growing naturally there.

This rises with a square shrubby stalk about three feet high, sending out several four-cornered branches, which are garnished with oval crenated leaves, rough on their upper side like the Dead Nettle, but veined on the under, which is of a pale green: these are placed opposite by pairs, as are also their branches. The flowers come out in whorls round the branches, in like manner as the former, but are not so long nor so deep coloured; they appear at the same season with the first, and continue as long in beauty.

Both these sorts are propagated by cuttings in Europe, for they do not produce any seeds here. If the cuttings are planted in July, after the plants have been so long exposed to the open air as to harden the shoots, they will take root very freely. They should be planted in a loamy border to an east aspect, and if they are covered closely with a bell or hand-glass to exclude the air, and shaded from the sun, it will forward their putting out roots; but when they begin to shoot, the glasses should be raised to admit the free air, to prevent their drawing up weak, and by degrees they must be exposed to the open air. As soon as they have taken good root they must be taken up, and each planted in a separate pot filled with soft loamy earth, and placed in the shade till they have taken new root; then they may be removed to a sheltered situation, where they may remain till October, when they must be removed into the green-house, and afterward treated as the Myrtle, and other hardy green-house plants, observing to water the first sort plentifully.

LEPIDIUM. Tourn. Inst. R. H. 215. tab. 103. Lin. Gen. Plant. 718. Dittander, or Pepperwort.

The CHARACTERS are,

The empalement of the flower is composed of four oval concave leaves, which fall off. The flower has four oval petals placed in form of a cross, which are much larger than the empalement, and six awl-shaped stamina the length of the empalement, two of which are shorter than the other, terminated by single summits. In the center is situated a heart-shaped germen, supporting a single style, crowned by an obtuse stigma. The germen afterward turns to a spear-shaped seed-vessel with two cells, divided by an intermediate partition, containing oblong seeds.

This genus of plants is ranged in the first section of Linnæus's fifteenth class, intitled Tetradinamia sili-culosa, the flower having four long and two shorter stamina, and the seeds being included in short pods.

The first sort grows naturally in moist places in many parts of England, so is now seldom cultivated in gardens. It hath small, white, creeping roots, by which it multiplies very fast, so as to render it difficult to eradicate the plant, after it has grown long in any place; the lower leaves are oval, spear-shaped, about three inches long, and one and a half broad toward the base, sawed upon the edges, having long foot-stalks. The stalks rise two feet high, they are smooth,

and

LEP

and send out many side branches; the leaves upon the stalks are longer, narrower, and more acute-pointed than the lower, and are not sawed on their edges. The flowers grow in close bunches toward the top of the branches, which come out from the side; they are small, and are composed of four small white petals, which appear in June and July, and the seeds ripen in the autumn. The whole plant has a hot biting taste like Pepper, and the leaves have been often used by the country people to give a relish to their viands instead of Pepper, from whence it had the appellation of Poor Man's Pepper.

This plant is easily propagated, for every piece of the root will grow and multiply wherever it is planted, so will become troublesome to root out after growing for some time in a garden. The leaves of this plant bruised and mixed with hog's lard, and applied as a cataplasim to the hip, help the sciatica; and chewed in the mouth, cause a great defluxion of rheum, so is said to help scrophulous tumours in the throat.

The second sort grows naturally in Austria and Italy; this hath a fleshy fibrous root, from whence arise several weak stalks about a foot and a half high, which are garnished with spear-shaped leaves, three inches long and one and a half broad, deeply cut in upon the edges; these are smooth, a little hoary, and embrace the stalks with their base; the flowers are small, white, and grow in loose bunches at the end of the branches. They flower from June till the beginning of September, and the seeds ripen in the autumn.

This is a perennial plant, which propagates very fast by its roots, and is seldom admitted into gardens.

The third sort grows naturally about Aleppo; this hath creeping roots, which extend to a great distance, so will soon spread over a large piece of ground. The leaves of this are longer and narrower than those of the former, and are less hoary; the flowers grow in loose bunches at the end of the branches; they are small and white like those of the first. This is a hardy perennial plant, which propagates by its creeping roots in as great plenty as either of the former.

The fourth sort grows naturally in the south of France, Italy, and Sicily, but is preserved in some English gardens for variety. This hath a long fleshy root, which runs deep into the ground, and sends out many oblong leaves, which are sawed on their edges, and spread flat on the ground; the stalks are slender, stiff, and branch out horizontally on every side; they rise about two feet high, and are garnished with very narrow entire leaves. The flowers come out in close small clusters at the ends of the branches; they are white, and appear in June and July, and the seeds ripen in the autumn. If the seeds are permitted to scatter, the plants will come up early in the spring, and require no other care but to keep them clean from weeds; the roots will abide several years if they are in a dry soil. This plant is also commended for its virtues in sciaticas, if bruised and mixed with hog's lard as the first, and from its virtues it obtained the title of Sciatica Cress.

The fifth sort grows naturally in Persia and Syria; this is supposed to be the true Mithridate Mustard of Dioscorides. It is an annual plant, whose lower leaves are winged, and finely cut into many segments; the stalks rise a foot high, dividing into many slender branches, which are garnished with heart-shaped leaves that are entire, and embrace the stalks with their base. The flowers grow in long loose spikes from the end of the branches; they are small, yellow, and appear in June and July, and the seeds ripen in September, soon after which the plant decays.

The seeds of this plant should be sown in the autumn, for those which are sown in the spring seldom flower the same year, and are often killed by the frost in winter; whereas those which are sown in the autumn, or the plants that rise from scattered seeds, will always flower about Midsummer, and the seeds ripen in August and September following. The plants re-

LEP

quire no other care but to thin them, and keep them clean from weeds.

The sixth sort is an annual plant, which grows naturally in Virginia, and also in all the islands of the West-Indies, where the inhabitants gather the leaves, and eat them in their fallads, as we do the Garden Cress.

The lower leaves of this sort are three inches long and one broad, sawed on their edges, and are of a light green, with a biting taste like Cress. The stalk rises a foot and a half high, sending out a great number of small side branches, which are garnished with narrow leaves regularly sawed on their edges, so as to resemble winged leaves; these sit close to the branches. The flowers are produced at the end of the branches in loose spikes; they are small and white, and are succeeded by roundish or heart-shaped compressed seed-vessels, which have a border round them. It flowers in June and July, and the seeds ripen in the autumn; this sort is easily propagated by seeds, which may be sown upon an open bed in April, where the plants are designed to remain; and when they come up, they will require no other care but to thin them where they are too close, and keep them constantly clean from weeds; or if the seeds are permitted to scatter in the autumn, the plants will come up very well, and may be treated in the same way as the other.

The seventh sort grows naturally in Asia, and also in Spain, from whence I have received the seeds. This is a biennial plant; the lower leaves which spread on the ground, are near two inches long, and about half an inch broad, indented on both sides in shape of a lyre, and curled on the edges; the stalks rise a foot high, and divide into a great number of slender branches, garnished with small oblong leaves, which are cut on their sides, and a little curled on their edges; the stalks and leaves are of a gray colour, inclining toward hoariness. The flowers are produced in clusters at the end of the branches; they are very small and white, appearing in July, and are succeeded by roundish bordered seed-vessels, which are compressed, and have two cells each, containing two small oblong seeds, which are ripe in the autumn.

This sort may be propagated by seeds in the same manner as the former; or if the seeds are permitted to scatter in the autumn, the plants will come up without care, and should be treated in the same way as the former sort; but this does not flower till the second year, so the plants should be left farther asunder.

The eighth sort grows naturally about Montpellier. It is a small annual plant, having a few wing-pointed leaves which spread on the surface of the ground; between which arises a naked stalk two or three inches high, supporting five or six small white flowers, each having four petals placed crosswise, and four stamina placed near the style; the germen afterward becomes a short capsule, including four or five roundish seeds.

If the seeds of this sort are sown in the autumn, the plants will flower in April and their seeds ripen in May; which, if permitted to scatter, the plants will come up in autumn, and require no other care but to thin them where they are too close, and weed them.

The ninth sort is also a low annual plant, which grows naturally on Putney-heath; the leaves of this are winged and entire, these are placed near the ground; the flower-stalks rise two inches high, supporting a few white flowers, whose petals are less than the em-palement, and are indented at their points. This flowers in May and June, and if their seeds are permitted to scatter, the plants will come up as the former.

The tenth sort is the Garden Cress, so much used in winter and spring fallads, and being so well known requires no description. There are three varieties of this, one with broad leaves, another with curled leaves, and the common sort which is used; the seeds of

LEU

of this should be sown in drills pretty close, in winter, on moderate hot-beds, but in spring and autumn on borders, and will soon be fit for use; therefore should be cut while young, otherwise it will be too rank.

The eleventh sort is a low shrubby plant, garnished with entire awl-shaped leaves, which are very narrow; these are placed alternately on the stalks; the foot-stalks of the flowers proceed from the wings, and also terminate the stalks; the flowers are white, and shaped like those of the other species.

This sort may be propagated by seeds or cuttings; the seeds should be sown in the spring on a bed of light earth, in the open air; and when the plants are fit to transplant, a few of them should be planted in pots, which may be sheltered in winter under a common frame; for in sharp winters, those plants which are exposed in the open air are frequently killed: the remaining plants should be planted in a sheltered situation in a dry rubbishing ground, where they will grow slowly, so will become more shrubby, and in less danger of suffering by cold.

The twelfth sort is an annual plant, which grows naturally in several parts of England, so is rarely preserved in gardens, being a plant of no great beauty or use; yet I have known it eaten in sallads, though the taste is very rank. The plants, when young, have some resemblance to the Swine's Cress. The stalks rise eight or ten inches high, supporting a number of small white flowers, shaped like those of the other species, which are succeeded by seeds like those of the Garden Cress, which, if permitted to scatter, will abundantly supply the place with young plants.

The thirteenth sort grows naturally in many warm countries, for it has come up in the earth which came from the Brasils, and from several parts of America, so that it may be found in many other parts. The leaves and stalks are much like those of the Garden Cress, but are more divided, and differ in smell and taste from it: the petals of the flowers are so small as to be almost imperceptible, and there appears but two stamina in each.

This sort is only cultivated in botanic gardens for variety; the seeds should be sown on a moderate hot-bed in the spring, and when the plants have obtained strength, they may be transplanted on a warm border, where they will flower and perfect their seeds.

LEPIDOCARPODENDRON. See PROTEA.

LETTUCE. See LACTUCA.

LEUCANTHEMUM. See ANTHEMIS.

LEUCOJUM. Lin. Gen. Plant. 363. Narcisso-leucojum. Tourn. Inst. R. H. 387. tab. 208. [*Λευκόνιον*, of *λευκόν*, white, and *ῥόδον*, a Violet; i. e. White Violet.] Snowdrop; in French, *Perce-neige*.

The CHARACTERS are,

It hath an oblong, obtuse, compressed spathe or sheath, which opens on the side. The flower is of the spreading bell-shape, cut into six parts, which join at their base. It hath six short bristly stamina, terminated by oblong, obtuse, four-cornered summits, which are erect. The roundish germen is situated under the flower, supporting a style which is thick and obtuse at the top, crowned by an erect bristly stigma. The germen afterward becomes a turbinate capsule with three cells, opening with three valves, and filled with roundish seeds.

This genus of plants is ranged in the first section of Linnæus's sixth class, which includes the plants whose flowers have six stamina and one style.

The SPECIES are,

1. LEUCOJUM (*Vernum*): *spatha uniflora, stylo clavato.* Lin. Sp. Plant. 289. *Snowdrop with a sheath inclosing one flower, with a key-shaped style.* Narcisso-leucojum vulgare. Tourn. Inst. R. H. 387. *Common great Snowdrop.*
2. LEUCOJUM (*Æstivum*): *spatha multiflora, stylo clavato.* Læfl. Lin. Sp. Plant. 289. *Snowdrop with many flowers in a sheath, and a key-shaped style.* Narcisso-leucojum pratense multiflorum. Tourn. Inst. R. H. 387. *Meadow Snowdrop with many flowers, commonly called the tall late Snowdrop.*

LEV

The first sort grows naturally in Switzerland and Germany, as also upon the mountains near Turin. This hath an oblong bulbous root, shaped like that of the Daffodil, but smaller; the leaves are flat, of a deep green, four or five in number, broader and longer than those of the small Snowdrop; between these arise an angular stalk near a foot high, which is naked, hollow, and channelled; toward the top comes out a sheath, which is whitish, opening on the side, out of which come two or three white flowers, hanging upon slender foot-stalks; these have but one petal, which is cut into six parts almost to the bottom, which are much larger than those of the small Snowdrop, and the ends of the segments of the petal are tipped with green, where they are of a thicker substance than in any other part. These flowers appear in March, soon after those of the small sort; they have an agreeable scent, not much unlike that of the flowers of Hawthorn; after the flower is past, the germen which is situated below the flower, swells to a Pear-shaped capsule with three cells, inclosing several oblong seeds.

The leaves of this sort decay toward the end of May, after which time the roots may be taken up and transplanted, for they should not be long kept out of the ground. It is propagated here by offsets, which the roots put out pretty plentifully when they are in a situation agreeable for them, and when they are not too often removed. They should have a soft, gentle, loamy soil, and an exposure to the east; the roots should be planted six inches asunder, and four or five inches deep, and must not be transplanted oftener than every third year.

The second sort is generally known by the title of late, or tall Snowdrop; this grows naturally in the meadows near Pisa in Italy, in Hungary, and also near Montpellier.

The root of this sort is nearly as large as those of the common Daffodil, and are very like them in shape; the leaves also are not unlike those of the Daffodil, and are more in number than those of the other sort; they are of a pale green, and keel-shaped at the bottom, where they fold over each other, and embrace the stalk, which rises a foot and a half high; at the top is situated a spathe (or sheath) which opens on one side, and lets out three or four flowers, which hang downward, upon pretty long foot-stalks; these are cut into six oval concave segments almost to the bottom, and are of a clear white, with a large green tip to each segment, which is of a thicker consistence than any other part of the petal; within are situated six awl-shaped stamina, with oblong yellow summits, standing erect round a very slender style, crowned by an obtuse stigma. These flowers appear the latter end of April or the beginning of May, and as all flowers in each sheath do not come out together, but following each other, so there is a succession of them for three weeks or longer, in cool weather. The flowers are succeeded by large triangular seed-vessels, having three cells, each containing two rows of seeds. This sort is generally propagated in England by offsets, for the plants raised by seeds will not come to flower in less than four years; and as the roots put out offsets in plenty, so that is the more expeditious method. These roots may be treated in the same way as the first sort, and should have a soft loamy soil, and be exposed only to the morning sun, where they will flower stronger, and continue longer in beauty, than when they are in an open situation, though they will thrive in almost any soil or situation.

LEUCOJUM BULBOSUM. See GALANTHUS.

LEVEL, a mathematical instrument serving to draw a line parallel to the horizon, not only for various uses in masonry, &c. but also to measure the difference of ascent and descent between several places, for the conveying of water, draining of fens, &c.

LEV

A water Level shews the horizontal line, by means of a surface of water, or other liquid, founded on this principle, That water always naturally places itself level.

The most simple instrument for this use is made of a long wooden trough, or canal, whose sides are parallel to its base, so that, being equally filled with water, the surface thereof shews the line of Level.

This Level is also made with two cups fixed to the two ends of a pipe three or four feet long; about an inch in diameter; by means whereof, the water communicates from the one to the other cup, and this pipe being moveable on its stand, by means of a ball and socket, when the two cups become equally full of water, the two surfaces mark the line of Level. Instead of cups, this instrument may be made with two short cylinders of glass three or four inches long, fastened to each end of the pipe with wax or mastich; then the pipe, being filled either with common or coloured water, will shew itself through the cylinder, by means of which the line of Level is determined; the height of the water, with respect to the center of the earth, being always the same in both cylinders. This Level is very commodious in levelling small distances.

If you would level any piece of ground that you can see from side to side, or from the middle to any side, set up your instrument in the middle of it, whether it be a water Level, or a ground Level with sights; place it so high, that you may see over the highest part of the ground half a foot or a foot; then set up a stake in the middle, so that the top may be exactly level with the sights; and another stake on the highest side, the top of which must be level with the middle stake; then either turn the Level, or look-back sight, and set up another stake on the lower ground level with the two first; then you will have three stakes standing in a Level.

Then keeping your Level true to the middle stake, turn it till it makes right angles with the three stakes, and set up two stakes on each side one Level with those three, then you will have five stakes in two lines set true level.

If the ground be large, you may set up two rows more by the Level, but five stakes are enough in a small ground.

When this is done, you may lay your Level aside, and look over the head of one to the head of another, and cause the person who assists you to put down stakes between two and two, till you have set as many stakes level in the ground as you think convenient; or you may use a rule, which being placed level with the head of the stake, you may look over that to the head of the other, and put stakes down between you and the other stake, to what number you please.

The ground being thus staked out with all the stakes heads level, and half a foot higher than the highest ground, in some grounds the middle stake, and the stakes in the cross line, will be the Level line the ground must be brought to; that is, abating the hill, and filling up the low side to the Level of the mid-line. But if the ground be very uneven, then you must measure over all the stakes, and take them middle high for their mean of Level, and, by the rule of three, proportion your ground to that.

As for instance: If a valley be ten poles in length, and two feet in depth from the strait line, and there be a hill five poles long; how many feet deep must a person sink those five poles to fill up the valley? This question may be resolved by the inverse or back rule of three, and will stand thus: As 5 to 2, so is 10 to 4.

$$\begin{array}{r} 5 \text{ — } 2 \text{ — } 10 \\ \quad \quad \quad 2 \end{array}$$

$$5)20(4$$

So that a person must go four feet deep in such a hill to make good such a valley.

If you are to abut the top of the hill four feet deep,

LIC

and two poles from the top of that hill; these four feet are to come out.

To perform this, set up a stake on the top of a hill two or three feet above ground, and another of the same height where the depth comes out, set down a stake three rods from that, till the head comes to be in a line with these two, and at that stake you must be one foot deep.

At six poles stake down another as before, and there you must be two feet deep: then stake down another at nine poles, and there you must be three feet deep, and you may set more stakes at equal distances, which will direct you so as that you cannot go amiss.

LEVITY is the privation or want of weight in any body, when compared with another which is heavier, in which sense it is opposed to gravity.

The schoolmen maintain, that there is such a thing as positive and absolute Levity, and impute this to the rise and emergency of bodies lighter in specie than the fluids wherein they rise.

But, besides that the common sense of mankind discovers, that Levity is only a relative term, we find that all bodies tend towards the earth, some slower, and some faster, in all fluids or mediums, whether water, air, &c.

Thus cork is said to be lighter than gold, because under equal dimensions of bulk the gold will sink in, and the cork swim upon the water.

Archimedes has demonstrated, That a solid body will float any where in a fluid of the same specific gravity, and that a lighter body will keep above a heavier.

The reason of this is, because bodies falling towards the earth, those which have a like number of equal parts, have equal gravity, since the gravity of the whole is the sum of the gravity of all its parts.

Now, two bodies having an equal number of equal parts, if under the same dimensions there are no intervals destitute of matter; whence it follows, that as no portion of matter is so small, but that body wherein it is contained may be wholly divided into parts equally small, there can be no reason for the descent of these, which will not hold equally for the descent of that.

Hence it may be concluded, that those bodies which do not equally gravitate under the same dimensions, do not contain the same equal portions of matter, and therefore when we see, that a cube of gold subsides in water, at the same time that an equal bulk of cork swims upon it, it is evident, that the gold must have a greater number of equal parts of matter under the same bulk than the cork, or the cork must have a greater number of vacuities than the gold, and that there are also in the water a greater number of vacuities than in the gold.

Hence we have a clear idea both of density or gravity, and of Levity, and know, that in a strict sense the latter cannot be accounted any thing positive, but a mere negation, or absence of body, which determines that body to be lighter than another which contains more matter.

LICHEN. Liverwort.

There being two sorts of this plant which are used in medicine, and one of those being accounted a sovereign remedy for the bite of mad dogs, I thought it would not be improper to mention them here, though they are plants which cannot be propagated by any method, except by paring up the turf of Grass whereon they grow, and laying it down on some moist shady place, where, if the turf takes root, and thrives, the plants will spread and do well.

The two Sorts are,

1. **LICHEN** (*Petræus*) *petræus latifolius*, five *Hepatica fontana*. C. B. P. *Common broad-leaved Liverwort*.
2. **LICHEN** (*Officinarium*) *terrestris cinereus*. Raii Syn. *As-coloured Ground Liverwort*.

The first sort grows on the sides of wells, and in moist shady places, not only on the ground, but on stones, bricks, or wood. Of this there are several varieties,

which are distinguished by the curious in botany; but as they are plants of no use, I shall not enumerate them.

The second sort (which is used to cure the bite of mad dogs) grows on commons and open heaths, where the Grass is short, and the ground almost bare, in most parts of England, especially on declivities, and on the sides of pits. This spreads on the surface of the ground, and, when in perfection, is of an Ash-colour, but as it grows old, it alters, and becomes of a dark colour. This is often carried into gardens with the turf which is laid for walks and slopes, and where the soil is moist and cool, it will spread, and be difficult to destroy, so that it renders the Grass unsightly; but this is the only method yet known to have it grow in gardens, where it is desired. This is esteemed a sovereign remedy for the bite of mad dogs, and hath been for many years used with great success. It was communicated to the Royal Society by Mr. George Dampier, whose uncle had long used this plant, to cure the bite of mad dogs on men and animals, with infallible success. The method of taking it he has delivered as followeth: "Take of the herb, and dry it either in an oven, by the fire, or in the sun; then powder it, and pass it through a fine sieve; mix this with an equal quantity of fine powdered pepper. The common dose of this mixture is four scruples, which may be taken in warm milk, beer, ale, or broth." He also advises, that the part bitten be well washed, as also the clothes of the person who was bit, lest any of the snivel, or drivel of the mad dog should remain. If the person bitten be full grown, he advises, that he be blooded before the medicine is taken, and to use the remedy as soon after the bite as possible, as also to repeat the dose two or three several mornings fasting.

L I G H T is used in various senses: 1. Sometimes it signifies that sensation which is occasioned in the mind by the view of luminous bodies.

2. For those properties in those bodies, whereby they are fitted to excite those sensations in us.

3. A certain action of the luminous body on the medium between that and the eye, by the means of which the one is supposed to act on the other, and this is called secondary Light, or derived Light, in distinction to that of luminous bodies, which is called primary or innate Light.

As to the phenomenon of light, philosophers have explained it several ways; Aristotle by supposing some bodies to be transparent, as air, water, ice, &c. The Cartesians have considerably refined upon this notion of Light, and own, that Light, as it exists in the luminous body, is nothing else but a power or faculty of exciting in us a very clear and vivid sensation; and Father Malebranche explains the nature of Light by a supposed analogy between it and sound, the latter of which is allowed to be produced by the shaking or vibration of the insensible parts of the sonorous body.

But the greatest discoveries into this wonderful phenomenon have been made by Sir Isaac Newton, that the primary light consists wholly in a certain motion of the particles of the lucid body, whereby they do not propel any fictitious matter supposed to be lodged in the hidden pores of transparent bodies, but throw off from the luminous body certain very small particles, which are emitted every way with great force. And the secondary or derived Light, not in a conatus, but in a real motion of these particles receding every way from the luminous body in right lines, and with an incredible velocity.

For it has been demonstrated by Mr. Reaumur, from the observation on the satellites of Jupiter, that the progress of Light from the sun to our earth is not above ten minutes, and therefore, since the earth is at least 10,000 of its own diameters distant from the sun, Light must run 10,000 of those diameters in a minute, which is above 100,000 miles in a second. And if a bullet, moving with the same celerity with which it leaves the muzzle of a cannon, requires

twenty-five years to pass from the earth to the sun, as Mr. Huygens has computed; then the velocity of Light will be to that of a cannon ball, as twenty-five years is to ten minutes, which is above 10,000 to 1: so that the particles of Light move above a million of times swifter than a cannon ball, from which rapidity of motion very strange effects may be produced; but Sir Isaac Newton has shewn, past contradiction, that the Light of the sun is near seven minutes in its passage to the earth, which is the space of 50,000,000, a velocity 10,000,000 times greater than that wherewith a ball flies out of the mouth of a cannon.

Sir Isaac Newton also observes, that bodies and Light act mutually on one another: bodies on Light, in emitting, reflexing, refracting, and inflecting it, and Light on bodies, by heating them, and putting their parts into a vibrating motion, wherein heat principally consists; for he observes, that all fixed bodies, when heated beyond a certain degree, emit Light and shine, which shining, &c. appears to be owing to the vibrating motion of the parts, and all bodies abounding in earthy and sulphureous particles, if they be sufficiently agitated emit Light, which way soever the agitation be effected.

The same great author observes, that there are but three affections of Light wherein the rays differ, viz. refrangibility, reflexivity, and colour; and those rays which agree in refrangibility, agree also in the other two, whence they may be well defined homogeneous. Again, the colours exhibited by homogeneous Light, he calls homogeneous colours, and those produced by heterogeneous Light, heterogeneous colours; from which definitions he advances several propositions:

1. That the sun's Light consists of rays differing by indefinite degrees of refrangibility.

2. That rays, which differ in refrangibility, when parted from one another, do proportionably differ in the colours which they exhibit.

3. That there are as many simple and homogeneous colours, as there are degrees of refrangibility, for to every degree of refrangibility belongs a different colour.

4. Whiteness, in all respects, like that of the sun's immediate Light, and of all the usual objects of our senses, cannot be compounded of simple colours, without an indefinite variety of them, for to such a composition there are required rays endued with all the indefinite degrees of refrangibility, which infer as many simple colours.

5. The rays of Light do not act one on another in passing through the same medium.

6. The rays of Light do not suffer any alteration of their qualities from refraction, nor from the adjacent quiescent medium.

7. There can be no homogeneous colours produced out of Light by refraction, which are not commixed in it before, since refraction changes not the qualities of the rays, but only separates those that have divers qualities by means of their different refrangibility.

8. The sun's Light is an aggregate of homogeneous colours, whence homogeneous colours may be called primitive or original.

Hence proceeds the whole theory of colours in plants and flowers.

Those parts, v. g. which are the most refrangible, constitute Violet colour, the dimmest and most languid of all colours.

And, on the contrary, those particles that are the least refrangible, constitute a ray or a red colour, which is the brightest and most vivid of all colours; the other particles being distinguished into little rays, according to their respective magnitudes and degrees of refrangibility, excite intermediate vibrations, and so occasion the sensations of the intermediate colours. See Sir Isaac Newton's Doctrine of Colours.

Perhaps these observations of Light may to some persons seem foreign to the subject matter of this book, yet, if thoroughly understood might probably be found very useful. The learned and curious enquirer into the business of vegetation, the Rev. Dr.

Hales,

Hales, in his treatise on that head, does, upon the query put by Sir Isaac Newton ["Are not gross bodies and Light convertible into one another? And may not bodies receive much of their activity from the particles of Light which enter their composition? The change of bodies into Light, and of Light into bodies, is very conformable to the course of nature, which seems delighted with transformations,"] add this query; "And may not Light also, by freely entering the expanded surfaces of leaves and flowers, contribute much to the ennobling the principles of vegetables?"

That Light has been found to be of infinite service to the growth of vegetables, has been fully proved by many experiments: 1. By painting the walls of the inside of a green-house black, whereby there will be no reflected rays of Light, when the weather becomes so cold, as that the shutters to the windows have been obliged to be kept shut a few days, the leaves of those plants which have been placed therein have dropped off.

And plants which have been placed in dark rooms, have been found to do the same. The earthing up plants to blanch them, whereby they become tender, and better for use; yet if these are not used, when properly blanched, will soon decay: the like will happen if plants are covered close, so as no Light can come to them, they will soon grow pale and sicken, and afterward decay.

How much the fine racy flavour of fruits is owing to Light is hard to say, but from a few experiments it appears, most of their rich juices are beholden to Light for their excellence; therefore we may truly aver, that Light is as necessary to promote vegetation as for animal œconomy.

LIGUSTICUM. Tourn. Inst. R. H. 323. tab. 171. Lin. Gen. Plant. 308. [takes its name of Liguria, because this plant, in old time, grew in greatest plenty near a river of Genoa, called Liguria.] Lovage; in French, *Livèche*.

The CHARACTERS are,

It hath an umbellated flower. The general umbel is composed of several smaller, which are also composed of other yet smaller. The general umbel has an involucre composed of seven unequal leaves. The perianthium of the flower is indented in five parts, sitting upon the germen. The flower hath five equal petals, which are inflexed at their points, and keel-shaped within. It hath five hairy stamina, which are shorter than the petals, terminated by simple summits. The germen, which is situated under the flower, supports two simple styles, crowned by simple stigmas. The germen afterward turns to an oblong fruit, divided into two parts, which is angular and channelled, containing two oblong smooth seeds.

This genus of plants is ranged in the second section of Linnæus's fifth class, which contains those plants whose flowers have five stamina and two styles.

The SPECIES are,

1. **LIGUSTICUM** (*Levisticum*) foliis multiplicibus, foliolis supernè incisis. Hort. Cliff. 97. Lovage with many leaves, whose lobes are cut outward toward the top. *Levisticum vulgare*. Mor. Hist. 3. p. 275. Common Lovage.
2. **LIGUSTICUM** (*Scoticum*) foliis biternatis. Lin. Sp. Plant. 250. Lovage with double trifoliate leaves. *Ligusticum Scoticum Apii folio*. Tourn. Inst. R. H. 324. Scotch Lovage with a Smallage leaf.
3. **LIGUSTICUM** (*Austriacum*) foliis bipinnatis, foliolis confluentibus incisis integerrimis. Lin. Sp. 360. Lovage with double winged leaves, whose lobes run together, and have entire segments. *Ligusticum cicutæ folio glabrum*. Tourn. Inst. R. H. 323. Lovage with a smooth Hemlock leaf.
4. **LIGUSTICUM** (*Lucidum*) foliis pinnatifidis, foliolis linearibus planis. Lovage with wing-pointed leaves, whose lobes are very narrow and plain. *Ligusticum Pyrenaicum, fœniculi folio lucidum*. Tourn. Inst. 324. Lovage of the Pyrenees, with a shining Fennel leaf.
5. **LIGUSTICUM** (*Peloponassiacum*) foliis multiplicatopinnatis, foliolis pinnatim incisis. Lin. Sp. 36. Lo-

vage with leaves many times winged, and lobes cut like wings. *Cicutaria laüfolia foetida*. C. B. P. 161. Broad-leaved, stinking, Bastard Hemlock.

The first sort is the common Lovage of the shops; this was formerly cultivated in the kitchen-gardens as an esculent herb, but has been long disused as such in England. It grows naturally upon the Appenines, and also near the river Liguria not far from Genoa; this hath a strong, fleshy, perennial root, which strikes deep into the ground, and is composed of many strong fleshy fibres covered with a brown skin; and has a strong, hot, aromatic smell and taste. The leaves are large, winged, and composed of many large lobes shaped like those of Smallage, but are larger, and of a deeper green. The lobes toward the top are cut into acute segments. The stalks rise to the height of six or seven feet; they are large and channelled, dividing into several branches, each being terminated by a large umbel of yellow flowers, which are succeeded by oblong striated seeds. It flowers in June and July, and the seeds ripen in autumn.

This is easily propagated by seeds, which should be sown in autumn soon after they are ripe; for when they are kept out of the ground till spring, they seldom grow the first year; when the plants come up and are fit to remove, they may be transplanted into a moist rich border, at about three feet distance from each other; and after they have taken new root, they will require no other care but to keep them clean from weeds. The roots will abide many years, and where the seeds are permitted to scatter, the plants will come up without care.

The roots, leaves, and seeds of Lovage, are heating and drying; they warm and comfort the stomach, expel wind, and provoke urine.

The second sort grows naturally near the sea in many parts of Scotland; this hath a biennial root, but of much less size than the former; the leaves are composed of broader and shorter lobes, each leaf having two or three trifoliate leaves, whose lobes are indented on their edges. The stalk rises about a foot high, sustaining a small umbel of yellow flowers on the top, shaped like those of the former; these appear in June, and are succeeded by oblong channelled seeds, which ripen in autumn. This plant may be cultivated in the same manner as the former.

The third sort grows naturally on the Alps; this is a perennial plant. The stalks rise about two feet high, and at every joint are bent alternately, first to one side, then to the opposite; at every joint they are garnished with doubly winged leaves, composed of small lobes which run into each other, and just above each leaf comes out a side branch; these, as also the principal stalks, are terminated by umbels of white flowers, which appear in June, and are succeeded by oblong channelled seeds, which ripen in autumn.

The fourth sort grows naturally on the Pyrenean Mountains; this hath a biennial root. The leaves are doubly winged. The lobes are very narrow, and finely divided. The stalks are strong, and rise a foot and a half high, garnished with shining winged leaves, and are terminated by pretty large umbels of whitish flowers, which appear in June, and the seeds ripen in September.

The fifth sort grows naturally on the Peloponessian Mountains; this hath a very thick fleshy root like that of Parsnep, which strikes deep in the ground. The leaves are very large, being composed of many winged leaves, whose lobes are cut into acute points; these are of a deep green, and, when bruised, emit a foetid odour. The stalks rise three or four feet high; they are very large and hollow, like those of Hemlock, and sustain at their top large umbels of yellowish flowers, in shape of a corymbus; these appear in June, and are succeeded by oblong channelled seeds which ripen in autumn.

This has by some persons been thought to be the Hemlock of the antients, their conjectures being founded upon the plant answering in many particu-

bars to the description, and also from the poisonous quality of this together with its foetid scent; and as this grows naturally in many parts of Asia, so they have been induced to believe it might be the same plant.

All these plants are preserved in botanic gardens for the sake of variety, but are seldom cultivated any where else; they rise easily from seeds, which should be sown in autumn, and the plants afterward treated in the same way as the first; they love a moist soil and a shady situation.

LIGUSTRUM. Tourn. Inst. R. H. 596. tab. 367. Lin. Gen. Plant. 18. Privet; in French, *Troène*.

The CHARACTERS are,

The flower has a small tubular empalement, cut at the top into four obtuse segments. It hath one funnel-shaped petal, with a cylindrical tube cut into four oval segments at the top, which spread open. It hath two stamina which stand opposite, terminated by erect summits which are the length of the tube of the petal, and one roundish germen supporting a short style, crowned by an obtuse bifid stigma. The germen afterward turns to a smooth round berry with one cell, inclosing two oblong seeds, flat on one side, but convex on the other.

This genus of plants is ranged in the first section of Linnæus's second class, which includes those plants whose flowers have two stamina and one style.

The SPECIES are,

1. **LIGUSTRUM** (*Vulgare*) foliis lanceolato-ovatis obtusis. Privet with spear-shaped, oval, obtuse leaves. *Ligustrum Germanicum.* C. B. P. 475. *The common Privet.*
2. **LIGUSTRUM** (*Italicum*) foliis lanceolatis acutis. Privet with spear-shaped leaves. *Ligustrum foliis majoribus & magis acuminatis toto anno folia retinens.* Pluk. Alm. 217. *Privet with larger and more acute-pointed leaves, which continue all the year, commonly called the Italian ever-green Privet.*

The first sort grows common in the hedges in most parts of England, where it rises fifteen or sixteen feet high, with a woody stem, covered with a smooth gray bark, sending out many lateral branches which are garnished with spear-shaped, oval, smooth leaves, ending with obtuse points; they are placed by pairs opposite, sitting close to the branches, and are of a dark green. The flowers are produced in thick spikes at the end of the branches; they are white, with one tubular petal cut at the top into four parts, which spread open. These come out in June, and are succeeded by small round black berries, which ripen in the autumn; each of these contain two seeds. The leaves of this sort frequently remain green till after Christmas, when they alter their colour and fall off. There are two varieties of this sort, one whose leaves are variegated with white, and the other hath leaves variegated with yellow; but in order to preserve these varieties, they should be planted in poor land; for if they are in a rich soil, they will grow vigorous and soon become plain.

The other sort grows naturally in Italy; this rises with a stronger stalk than the former, the branches are less pliable and grow more erect; their bark is of a lighter colour; the leaves are much larger, and end in acute points; they are also of a brighter green, and continue upon the shrubs in verdure, till they are thrust off by the young leaves in the spring, as the Phillyrea and most other Evergreens do; so that it is undoubtedly a distinct sort, though many have supposed they were the same. The flowers of this are rather larger than those of the common sort, and are not often succeeded by berries in this country.

The leaves and flowers of the first sort are used in medicine; they are reckoned to be cooling, drying, and restringent, good for ulcers and inflammations of the mouth and throat, bleeding of the gums, and relaxation of the uvula.

This shrub is frequently cultivated in the nurseries near London, to furnish the small gardens and balconies in the city, it being one of the few plants which will thrive in the smoke of London; but although it will live some years in the close part of the town, yet

it seldom produces flowers there after the first year, unless it is in some open places, where there is a free air. In the country, the leaves of this plant will continue green great part of the winter. It flowers in June, and the berries ripen in autumn, which generally hang upon the branches till Christmas.

The Italian sort is now generally preferred to the common sort for planting in gardens; the leaves being larger and continuing green all the year, renders it more valuable; and being so hardy as to resist the greatest cold in this country, it may be planted in any situation where the common sort will thrive. I have frequently planted it under the dropping of large trees; where I find it will thrive better than most other shrubs.

I cannot but think this sort which is the most common in Italy, is the *Ligustrum* mentioned by Virgil in the second Eclogue; and my reason for it is, that as the flowers of this shrub are of a pure white, but fall off very soon; they are by no means proper to gather for garlands, &c. and the berries being of a fine black colour, and continuing long upon the plants, make a fine appearance. To confirm that these berries were gathered for use; we find in several authors of undoubted credit, that they were used in dyeing; as also that the best ink was made of these berries.

Besides, is it not much more reasonable to suppose, that Virgil would rather draw his comparison from the flowers and fruit of the same plant, when he is warning the youth not to trust to his beauty, than to mention two different plants, as has been generally supposed? for here are the white flowers of the Privet appearing early in the spring, which is an allusion to youth; but these are of short duration, soon falling away; whereas the berries, which may be applied to mature age, are of long continuance, and are gathered for use.

These plants are easily propagated by laying down their tender shoots in autumn, which in one year's time will be rooted enough to transplant; when they may be removed to the places where they are designed to remain, or planted in a nursery for two or three years, where they may be trained for the purposes designed.

They are also propagated by suckers, which these plants send forth in great plenty; but these are too apt to put out a great number of suckers from their roots, so are not easily kept within bounds; nor do the plants rise so high as those which are propagated by layers, therefore this method should be preferred.

They may also be propagated by cuttings, which, if planted in the autumn on a shady border and in a loamy soil, will take root very freely, and may be afterward treated in the same way as the layers.

But the strongest and best plants, are those which are raised from seeds; indeed, this is a much more tedious method than the other, so is seldom practised, for the seeds generally lie a year in the ground before they vegetate; therefore, whoever would propagate the plants in this method, should gather the berries when ripe, and put them into a pot with sand between them, and bury the pot in the ground, as is practised for Holly berries and Haws; and after they have laid a year in the ground, take them up in the autumn, and sow them on a border exposed to the east, where the plants will come up the following spring, and these will make great progress after they have gotten some strength, so will grow upright, and not send out suckers like the other.

Formerly these plants were greatly in use for hedges, but since so many others of great beauty have been introduced, which are much preferable to these for such purposes, they have been entirely rejected, the trouble of keeping them in order being very great; nor are the hedges made with them ever so thick and handsome, as those made with divers other plants.

The two variegated kinds are pretty varieties amongst other striped shrubs. These may be propagated by budding, or inarching them upon the plain sort, as also

also by laying down their branches; but as they seldom shoot so fast, as to produce any branches proper for layers, the other method is chiefly used. The silver striped sort is somewhat tenderer than the plain, but will endure the open air, if planted in a dry soil and in a warm situation.

LILIUM. Tourn. Inst. R. H. 369. tab. 191. Lin. Gen. Plant. 371. [takes its name of λῖον, smooth, polished, because its leaves are, as it were, polished; or of λειρὸν, which signifies the same thing,] the Lily; in French, *Lis*.

The CHARACTERS are,

The flower has no empalement; it hath six petals, which are narrow at their base, but are broad, obtuse, and reflexed at their points. The flower is of the open bell-shape, the petals are thick, obtuse, and keel-shaped; on their back each petal has a narrow longitudinal nectarium at their base. It hath six stamina which are erect and shorter than the petals, terminated by oblong prostrate summits, with a cylindrical oblong germen having six furrows, supporting a cylindrical style the length of the petals, crowned by a thick triangular stigma. The germen afterward becomes an oblong capsule with six rough furrows hollowed at the top, having three cells which are filled with flat half round seeds, lying above each other in a double order.

This genus of plants is ranged in the first section of Linnæus's sixth class, which includes those plants whose flowers have six stamina and one style.

The SPECIES are,

1. LILIUM (*Candidum*) foliis sparsis, corollis campanulatis erectis, intus glabris. Hort. Cliff. 120. *Lily with sparsed leaves, and a bell-shaped erect flower which is smooth within.* Liliun album, flore erecto & vulgare. C. B. P. 76. *Common white Lily with an erect flower.*
2. LILIUM (*Peregrinum*) foliis sparsis, corollis campanulatis cernuis, petalis basi angustioribus. *Lily with sparsed leaves, and a bell-shaped nodding flower, whose petals are narrower at their base.* Liliun album, floribus dependentibus, sive peregrinum. C. B. P. 76. *White foreign Lily with pendent flowers.*
3. LILIUM (*Bulbiferum*) foliis sparsis, corollis campanulatis erectis, intus scabris. Hort. Cliff. 120. *Lily with sparsed leaves, and an erect bell-shaped flower, rough within.* Liliun purpureo-croceum majus. C. B. P. 76. *Greater Lily with a purple Saffron-coloured flower, commonly called Orange Lily.*
4. LILIUM (*Humile*) humile, foliis linearibus sparsis, corollis campanulatis erectis, caule bulbifero. *Dwarf Lily with narrow sparsed leaves, erect bell-shaped flowers, and a stalk bearing bulbs.* Liliun bulbiferum minus. C. B. P. 77. *Smaller bulb-bearing Lily, by some called the fiery Lily.*
5. LILIUM (*Pomponium*) foliis sparsis subulatis, floribus reflexis, corollis revolutis. Hort. Cliff. 120. *Lily with awl-shaped sparsed leaves and reflexed flowers, whose petals are turned backward.* Liliun rubrum angustifolium. C. B. P. 78. *Narrow-leaved red Lily or Martagon.*
6. LILIUM (*Angustifolium*) foliis linearibus sparsis, pedunculis longissimis. *Lily with narrow sparsed leaves, and very long foot-stalks to the flowers.* Liliun brevi & gramineo folio. C. B. P. 79. *Lily with a short Grass leaf, commonly called Martagon of Pompony.*
7. LILIUM (*Chalcedonicum*) foliis sparsis lanceolatis, floribus reflexis, corollis revolutis. Hort. Cliff. 120. *Lily with sparsed spear-shaped leaves, and reflexed flowers whose petals turn backward.* Liliun Byzantinum miniatum. C. B. P. 78. *Lily of Byzantium with a carmine flower, commonly called the scarlet Martagon.*
8. LILIUM (*Superbum*) foliis sparsis lanceolatis, floribus pyramidalis reflexis, corollis revolutis. *Lily with sparsed spear-shaped leaves, and pyramidal reflexed flowers,*

whose petals turn backward. Martagon multis & magnis floribus luteis alios superans. Suvert. Icon. Pl. 57. *The great yellow Martagon.*

9. LILIUM (*Martagon*) foliis verticillatis, floribus reflexis, corollis revolutis. Hort. Cliff. 120. *Lily with leaves growing in whorls, and reflexed flowers whose petals turn backward.* Liliun floribus reflexis montanum. C. B. P. 77. *Mountain Lily with reflexed flowers, commonly called purple Martagon.*
10. LILIUM (*Hirsutum*) foliis verticillatis hirsutis, floribus reflexis, corollis revolutis. *Lily with hairy leaves growing in whorls, and reflexed flowers whose petals turn backward.* Liliun floribus reflexis alterum lanugine hirsutum. C. B. P. 718. *Another Lily with reflexed flowers which is hairy and downy, commonly called the red Martagon.*
11. LILIUM (*Canadense*) foliis verticillatis, floribus reflexis corollis campanulatis. Lin. Sp. Plant. 303. *Lily with leaves growing in whorls, and reflexed bell-shaped flowers.* Liliun, sc. martagon Canadense maculatum. Mor. Hist. 2. p. 408. *Lily, or Martagon of Canada with spotted flowers.*
12. LILIUM (*Campschatense*) foliis verticillatis, floribus erectis, corollis campanulatis. Amoen. Acad. 2. p. 348. *Lily with leaves growing in whorls, and an erect bell-shaped flower.*
13. LILIUM (*Philadelphicum*) foliis verticillatis brevibus, corollis campanulatis, unguibus petalorum angustioribus, floribus erectis. Icon. tab. 165. *Lily with very short leaves growing in whorls, and bell-shaped flowers whose petals are very narrow at their base.*

There is a greater variety of Martagons than are here mentioned, but as they are supposed to be only accidental arising from culture, so I thought it would be to little purpose to insert them here; therefore I shall only give their common titles hereafter.

The common white Lily is so well known as to need no description; this grows naturally in Palestine and Syria, but has been long cultivated in all the gardens of Europe. It is so hardy that no frost ever injures the roots in England, and it propagates so fast by offsets from the roots, that it is become so common as to be little regarded, though there is great beauty in the flowers, and they emit an agreeable odour. Of this sort there are the following varieties:

The white Lily striped with purple.

The white Lily with variegated leaves.

The white Lily with double flowers.

These are varieties which have accidentally risen from culture; the sort with variegated flowers has not been in England much more than thirty-five years, but is now very common in most of the gardens, and is by some persons esteemed for the variety of its purple stripes; but as the pure white of the flower is stained by the purple, so as to appear of a dull colour, therefore many prefer the common white Lily.

The sort with variegated leaves is chiefly valued for its appearance in winter and spring, for as the leaves come up early in the autumn, which spread themselves flat on the ground, and being finely edged with broad yellow stripes, they make a pretty appearance during the winter and spring months. The flowers are the same as those of the common sort, but appear earlier in summer, which may be occasioned by the roots being weaker than those of the plain sort, for all variegated plants are weaker than those which are plain.

The white Lily with double flowers is less valuable than either of the other, because their flowers never open well, unless they are covered with glasses to shelter them from the rain and dew, so often rot without expanding. These flowers have none of the agreeable odour which the single sort is valued for, even when they open the fairest; for as by the multiplicity of petals in the flowers, the parts of generation are destroyed, so there is a want of the fecundating powder from whence the odour is sent out.

The roots, leaves, and flowers of the common white Lily are used in medicine; the roots are frequently used to soften, ripen, and digest tumours and hard swellings. Matthioli says, that the distilled water

of the flowers, is properly and successfully given to women in hard labour; and the distilled water of the leaves is of great use in distempers of the lungs.

The white Lily with dependent flowers, was originally brought from Constantinople. This is by some supposed to be only a variety of the common sort, but is undoubtedly a distinct species; the stalk is much slenderer than the common, the leaves are narrower and fewer in number; the flowers are not quite so large, and the petals are more contracted at their base; these always hang downward, whereas those of the common sort grow erect. The stalks of this kind sometimes are very broad and flat, and appear as if two or three were joined together; when this happens, they sustain from sixty to a hundred flowers, and sometimes more; this has occasioned many to think it a different sort, who have mentioned this with broad stalks and many flowers as a distinct species, though it is accidental, for the same root scarce ever produces the same two years.

These sorts are easily propagated by offsets, which the roots send out in so great plenty, as to make it necessary to take them off every other, or at most every third year, to prevent their weakening the principal roots. The time for removing the roots is at the end of August, soon after the stalks decay; for if they are left longer in the ground, they will soon put out new fibres and leaves, when it will be improper to remove them, because that will prevent their flowering the following summer. They will thrive in almost any soil or situation, and as they grow tall and spread, so they must be allowed room; therefore in small gardens they take up too much space, but in large borders they are very ornamental.

The common Orange or red Lily, is as well known in the English gardens as the white Lily, and has been as long cultivated here. This grows naturally in Austria and some parts of Italy. This sort multiplies very fast by offsets from the roots, and is now so common, as to be almost rejected; however, in large gardens these should not be wanting, for they make a good appearance when in flower, if they are properly disposed. Of this sort there are the following varieties:

The Orange Lily with double flowers.

The Orange Lily with variegated leaves.

The smaller Orange Lily.

These varieties have been obtained by culture, and are preserved in the gardens of florists. They all flower in June and July, and their stalks decay in September, when the roots may be transplanted, and their offsets taken off, which should be done once in two or three years, otherwise their bunches will be too large, and the flower-stalks weak. This doth not put out new leaves till toward spring, so that the roots may be transplanted at any time after the stalks decay till near Christmas. It will thrive in any soil or situation, but will be strongest in a soft gentle loam not too moist.

The bulb-bearing fiery Lily seldom rises much more than half the height of the former; the leaves are narrower, the flowers are smaller, and of a brighter flame colour; they are few in number, and stand more erect. These come out a month before the common sort, and the stalks put out bulbs at most of the joints, which, if taken off, when the stalks decay, and planted, will produce plants, so that it may be propagated in plenty. There are several varieties of this, which are mentioned as distinct species, but are supposed to have been produced by culture.

These are,

The greater broad-leaved bulb-bearing Lily.

The many-flowered bulb-bearing Lily.

The small bulb-bearing Lily.

The hairy bulb-bearing Lily.

All these sorts of Lilies will thrive under the shade of trees, so may be introduced in plantations, and on the borders of woods, where they will have a good effect during the time they are in flower.

There is a great variety of the Martagon Lily;

these differ from the common Lilies, in having their petals reflexed backward in form of a Turk's turban, from whence many give them the title of Turk's Cap. In the gardens of the florists, particularly those in Holland, they make a great variety of these flowers, amounting to the number of thirty or upward; but in the English gardens, I have not observed more than half that number, and most of these are accidental, for those before enumerated, are all that I think may be supposed specifically different. However, for the sake of such as are curious in collecting these sorts of flowers, I shall here mention all those varieties which are to be found in the English gardens.

The common Martagon with double flowers.

The white Martagon.

The double white Martagon.

The white spotted Martagon.

The Imperial Martagon.

The early scarlet Martagon.

The Constantinople Vermillion Martagon.

The common Martagon with red flowers, which is the fifth sort before enumerated, has very narrow leaves, growing without order. The stalk rises near three feet high, sustaining at the top eight or ten bright red flowers, which stand at a distance from each other. These appear in June, and the stalks decay in August, soon after which time the roots may be transplanted.

The sixth sort is called Martagon of Pompony; the stalks of this rise higher than those of the former, the leaves are shorter, and set closer upon the stalks; each of these stalks sustain from fifteen to thirty flowers, of a very bright red, approaching to scarlet. The foot-stalks of the flowers are very long, so that the head of flowers spreads out very wide; these hang downward, but their petals are reflexed quite back. This flowers soon after the fifth sort.

The seventh sort is commonly known by the title of Scarlet Martagon; this rises with a stalk from three to four feet high; the leaves are much broader than those of the former sorts, and appear as if they were edged with white; they are placed very closely upon the stalks, but without any order. The flowers are produced at the top of the stalks; they are of a bright scarlet, and are seldom more than five or six in number. This flowers late in July, and in cool seasons will continue in beauty great part of August.

The eighth sort rises with a strong stalk from four to five feet high, garnished with leaves as broad as those of the last mentioned, which stand without order; the flowers are produced in form of a pyramid, on the upper part of the stalk. When the roots of this kind are strong, they produce forty or fifty flowers upon each stalk; they are large, of a yellow colour, spotted with dark spots, so make a fine appearance; but the flowers have so disagreeable strong scent, that few persons can endure to be near them, which has occasioned their being thrown out of most English gardens. This flowers the latter end of June.

The ninth sort is frequently called the Purple Martagon, though in most of the old gardens it is known simply by the title of Turk's Cap. This rises with a strong stalk from three to four feet high, garnished by pretty broad leaves, which stand in whorls round the stalk, at certain distances. The flowers are of a dark purplish colour, with some spots of black; they are produced in loose spikes on the top of the stalks. This flowers in June; the flowers of this sort have a very disagreeable odour when near, but it is not so offensive as the former sort.

The tenth sort is very like the former, but the leaves are narrower, the whorls stand farther asunder, the leaves and stalks are somewhat hairy, and the buds of the flowers are covered with a soft down: the flowers are of a brighter colour with few spots, and come out earlier in the summer, though the stalks appear much later above ground. This flowers early in June, and the stalks decay in August.

The eleventh sort is commonly called the Canada Martagon, as it was first brought to Europe from thence,

but

but it grows naturally in most parts of North America. The roots of this are oblong and large, made up of scales like the other sorts; the stalks rise from four to five feet high, garnished with oblong pointed leaves placed in whorls round the stalk. The flowers are produced toward the top of the stalk; they are large, of a yellow colour, spotted with black, which are shaped like the flowers of the Orange Lily; the petals of them are not turned backward so much as those of the other sorts of Martagon. This flowers the beginning of August, and when the roots are large, the stalks have a good number of flowers, so make a fine appearance. There are two varieties of this, one with larger and deeper coloured flowers than the other, but they are supposed to have accidentally come from seeds.

The twelfth sort grows naturally in North America, and is also mentioned to grow at Campschatki. This hath erect flowers shaped like those of the Canada Martagon, but the petals of this are oval, not narrowed at their base as are those, and sit close to the foot-stalk; the flowers are of a deeper colour, and not so much spotted as the other sort. It flowers in July, and the stalks decay in the autumn.

This sort is at present rare in England, being in very few gardens. It was sent me a few years ago from Maryland, but after it had flowered the root perished.

The thirteenth sort was sent me from Pennsylvania by Mr. John Bartram, who found it growing naturally in that country. The root of this is smaller than those of the other sorts; it is scaly and white; in the spring it sends out one upright stalk near a foot and a half high; the leaves come out in whorls round the stalks, at distances; they are short, pretty broad, and have obtuse points. The stalk is terminated by two flowers which stand erect, upon short separate foot-stalks; they are shaped like the flowers of the bulb-bearing fiery Lily, but the petals are narrower at their base, so that there are spaces between each, but upward they enlarge and join, forming a sort of open bell-shaped flower; their petals are spear-shaped, so are contracted at the top, where they terminate in acute points. The flowers are of a bright purple colour, marked with several dark purple spots toward their base. In the center of the flower is situated a six-cornered germen, supporting a strong style, crowned by a three-cornered stigma; round this are situated six awl-shaped stamina, terminated by oblong prostrate summits; these are a little shorter than the style. The germen afterward turns to an oblong capsule with three angles, blunt at the top, divided into three cells, filled with flat seeds lying over each other. It flowers in July, and the seeds ripen the latter end of September.

This sort is at present very rare in the English gardens, but as it has ripened seeds the last season here, so it may in a few years become very common. As this sort grows in a small compass, and the flowers have no ill scent, it is proper furniture for the borders of small gardens. The stalks of this decay soon after the seeds are ripe, when it will be a proper time to remove the roots, for these do not put out new fibres till after Christmas. The roots of this kind do not put out many offsets, so that unless it is propagated by seeds, it cannot be increased in any plenty.

All the sorts of Martagon may be propagated by offsets from the roots, in the same way as the common Lily, which some of the sorts produce in as great plenty; but there are others which send out very few offsets, which occasion their present scarcity. The roots of all the sorts of Martagon may be safely taken up when their stalks decay; and if there is a necessity for keeping the roots out of the ground, if they are wrapped in dry Moss, they will keep perfectly well for two months; so that if the roots are to be transported to a distant place, this precaution of wrapping them up is necessary; but where they are to be planted in the same garden, there will be no occasion for this, especially if they are not kept too long out of the

ground; for if the place is ready to receive the roots, they should be planted the beginning of October; so if the roots are put in a dry cool place, they will keep very good without any further care; but if the ground is not ready to receive them till later in the year, then it will be proper to cover the roots with dry sand, or wrap them in Moss to exclude the air, which, if they are much exposed to, will cause their scales to shrink, which weakens the roots, often causing a mouldiness, and is sometimes the occasion of their rotting.

These roots should be planted five or six inches deep in the ground, especially if the soil is light and dry; but where the ground is moist, it will be proper to raise the borders in which these are to be planted, five or six inches above the level of the surface of the ground; for if the water rises so high in winter as to come near the roots, it will cause them to rot; and where the soil is naturally stiff and subject to bind, there should be a good quantity of sea-coal ashes or rough sand, well mixed in the border, to separate the parts, and prevent the ground from binding in the spring, otherwise the roots will not send up very strong stalks, nor will they make so good increase.

As the Canada Martagon, the Martagon of Pompony, and the last sort, are somewhat tenderer than the others, so if in very severe winters the surface of the ground over them is covered with old tanners bark or sea-coal ashes, it will be a good way to secure them from being injured by the frost; and in the spring the covering may be removed, before the roots shoot up their stalks.

The tall growing sorts of these are only proper for large gardens, so they may be intermixed with the white and Orange Lilies, the tall growing Irises, and other flowers of the same growth; where, if they are not too much crowded, and are properly disposed, they will make a good appearance; and as they flower one after another, so they may be disposed according to their seasons of flowering. There are some of the common Martagons hardy enough to thrive under the shade of trees, so they may be disposed in wilderness quarters, with the common sort of Lilies, where they will have a good effect.

The roots of all these kinds must never be transplanted after they have made any shoots, for that will so much weaken them (if it does not entirely kill them) as not to be recovered in less than two or three years, as I have experienced to my cost; for being obliged to remove a fine collection of these roots early in the spring, I lost a great part of them, and the others were long recovering their strength.

All the sorts of Lilies and Martagons may be propagated by sowing their seeds, by which method some new varieties may be obtained, provided the seeds are saved from the best sorts; especially the Martagons, which are more inclinable to vary than the other Lilies. The manner of sowing them is as follows:

You must be provided with some square boxes about six inches deep, which should have holes bored in their bottoms to let the wet pass off: these boxes should be filled with fresh light sandy earth, and in the beginning of October, soon after the seeds are ripe, you must sow them thereon pretty thick, covering them over with light sifted earth about half an inch; then place the boxes where they may have the morning sun only, observing if the season should prove dry, to refresh them often with water, as also to pull out all weeds which may be produced. In this situation the boxes should remain until the beginning of November, when you must remove them where they may have as much sun as possible, as also be screened from the cold north and east winds during the winter season; but in the spring of the year, about the beginning of April, you must remove the boxes into their former position; for now the young plants will appear above ground, which are impatient of too much heat, besides, the earth in the boxes will dry too fast at this season, if exposed to the full sun at noon.

You must also observe at this season to keep them entirely

entirely clear from weeds, as also to refresh them gently with water, if the season should prove dry, but this must be done sparingly and with caution. In this place you should let the boxes remain until the beginning of August; at which time you should prepare some beds of the above mentioned fresh light earth, which must be levelled very even; then take the earth out of the boxes, together with the small bulbs, and strew it equally over the beds, covering it over about half an inch thick with fine sifted earth; and if the season should prove very hot and dry, you would do well to shade the beds in the middle of the day from the great heat of the sun, and refresh them now and then with water.

You must also observe to keep them entirely clear from weeds, and if the following winter should prove very cold, you must cover the beds with Peas-haulm, or some other light covering, to keep out the frost, which would prejudice the roots, if suffered to enter deep into the ground (especially while they are so young:) but you must never let the covering remain on in mild weather, which would also be very injurious to them.

The end of February, or the beginning of March, when the hard frosts are over, you should gently clear off the earth upon the surface of the beds (which, during the winter season, will often have contracted a mossiness;) and sift a little fresh earth equally over the beds, which will greatly encourage the roots; but in doing this, you must be very careful not to stir the ground so deep as to disturb or injure the roots; nor should you defer doing it too late, lest the shoots should be coming up, which, by this operation might be broken and greatly hurt; and as the season advances, you must be careful to clear them from weeds, and in dry weather to water them gently, but they should not have it in great plenty; and in very hot days, if you shade them from the sun, it will be of great service to them; but this need not be done till the latter end of April or the beginning of May, when the season is sometimes very hot and dry. When their leaves are quite decayed, you should stir the surface of the beds again (but do not go too deep) which will prevent the weeds from growing very fast, and be of service to the roots; and in September you must sift some more fresh earth over the beds about half an inch thick, and in winter and spring you must manage them as was directed for the preceding year.

In September following these roots will require to be transplanted to a greater distance, when you must prepare some beds of the same fresh light earth as was before directed, making them level; then take up the roots and transplant them into the beds, placing them about eight inches asunder, observing to put the roots with their buds uppermost, and about four inches below the surface.

This work should be done when the weather is moist, for if the roots are transplanted in a very dry season, and there doth not happen rain soon after, they will take a mouldiness which many times rots them.

You must also observe, as was before directed, to keep the beds entirely clear from weeds; and in winter, if the frost should be very severe, you must cover them with Peas-haulm or decayed tan, to prevent the roots from being injured thereby; and in the spring you should take off the covering, also the earth from the surface of the beds, as before, laying some fresh thereon, and so continue the summer and winter's work, as before.

The second year after being planted in these beds, the strongest roots will begin to flower; at which time, if you observe any peculiar varieties, you should put down a stick by each of these roots to mark them; which may be taken up when their leaves are decayed, and removed into the borders of the flower-garden, or transplanted into other beds at a greater distance, to encourage them to flower strong. But you cannot be so good a judge which of those will be

good by their first flowers, therefore you should never reject any of them until they have flowered two years; for many times, some of these flowers will make but a mean appearance the first year, and afterwards become fair handsome flowers when they have obtained strength; so that you should suffer all such, of whose worth you are not assured, to remain undisturbed two years, that you may be ascertained which of them are worth preserving; these should be removed into the flower-garden at a proper season, but the ordinary ones may be rejected, or planted in shady outer walks, where, though they are mean flowers, they will appear well enough.

LILIUM SUPERBUM. See GLORIOSA.

LIME-TREE. See TILIA.

LIMODORUM. Flor. Virg. 110. Lin. Gen. Plant. 904. Helleborine. Tourn. Inst. R. H. 436. tab. 249. Bastard Hellebore.

The CHARACTERS are,

It hath a single naked flower-stalk, arising immediately from the root. The flowers have no empalement, but a spathe (or sheath) situated below them. The flower is composed of five oval petals, which are dissimilar. The side petals spread open, but the two upper are connected together; the lower one is keel-shaped, so that it has much the appearance of a butterfly flower. Within the petals is situated a concave nectarium of one leaf, which is as long as the petals. It has two stamina, which are as long as the petals, terminated by two oval summits. It hath a column-shaped germen situated under the flower, which is as long as the petals, supporting a slender style, fastened to the stamina, crowned by a funnel-shaped stigma. The column-shaped germen afterward turns to a capsule of the same form, opening with three valves, having one cell, in which are lodged four or five roundish seeds.

This genus of plants is ranged in the first section of Linnæus's twentieth class, which includes those plants whose flowers have but two stamina, which are connected with the style.

We have but one SPECIES of this genus at present in England, viz.

LIMODORUM (Tuberosum) foliis longis angustis sulcatis & acuminatis, pedunculis longissimis. *Limodorum with long narrow leaves ending in acute points, and a very long foot-stalk to the flower. Helleborine Americana, radice tuberosa, foliis longis angustis, caule nudo, floribus ex rubro pallide-purpureiscentibus.* Martyn. Cent. 1. Pl. 50. Icon. tab. 165. *American Bastard Hellebore with a tuberoso root, long narrow leaves, a naked stalk, and flowers of a red and pale purplish colour.*

This plant grows naturally in Jamaica, especially on the north side of that island, from whence many of the roots were sent me by the late Dr. Houstoun, with the following title, *Helleborine purpurea, tuberosa radice.* Plum. Cat. 9. so that it is the same plant with Plumier's. It also grows naturally in the French Islands of America. The roots of this were afterward brought me from the Bahama Islands, where it was found growing naturally; and it was since sent me from Pennsylvania, by Mr. John Bartram, who found it growing naturally in that country.

The root of this plant is shaped like that of the true Saffron Crocus, but the outer cover is of a darker brown colour; from this comes out two or three leaves, according to the size and strength of the root; these are nine or ten inches long, and near three quarters of an inch broad in the middle, being contracted toward both ends, terminating with long acute points, folding over each other at their base; they have five longitudinal furrows, like the first leaves of young Palms; these leaves come out in the spring, and frequently decay the following winter; but when the plants are kept in a warm stove, they are not very long destitute of leaves. The flower-stalk arises immediately from the root, on one side of the leaves; this is naked, smooth, and of a purplish colour toward the top. It is near a foot and a half high, and terminated by a loose spike of purplish red flowers,

standing

standing upon short foot-stalks; they are composed of five or six petals, the two upper are connected together, forming a sort of helmet, the two side petals expand like the wings of a butterfly flower, and the lower forms a sort of keel. In the center of the petals is situated a column-shaped germen, which rises from the base of the petals, supporting a slender style, to which adhere two stamina, terminated by oval summits, as the style is by a funnel-shaped stigma; after the flowers are faded, the germen becomes a three-cornered column-shaped capsule, with one cell, opening with three valves, containing several roundish seeds, but these seeds are rarely produced in England.

This plant is not constant to any particular season of flowering; for sometimes it has flowered in April and May, and in other years it has not flowered till September or October; but the most usual time of its flowering is in June and July, when the flowers appear early in the spring; they are succeeded by seed-vessels, which sometimes ripen in this country.

There are several other species of this genus mentioned by Father Plumier, but I have only seen one more than this here mentioned, which had oval obtuse leaves, furrowed in the same manner as the leaves of this sort, but were of a thicker consistence; the flowers of this I have not yet seen. The root was sent me from Maryland, where it grew naturally in a thicket.

The sort here described is too tender to thrive in the open air in England, and although with care it may be preserved in a warm green-house, yet it seldom flowers in such a situation; so that to have it in perfection, it is necessary to keep it in the tan-bed in the stove in winter; and if in summer the pots are plunged in a tan-bed under a deep frame, the plants will thrive, and flower as strong as in their native soil.

It is propagated by offsets from the root, which are sent out pretty freely when the plants are in vigour; these should be taken off, and the roots transplanted when they are the most destitute of leaves. The roots should have a soft loamy soil, and must have but little water, especially in winter.

LIMODORUM. See ORCHIS.

LIMON. Tourn. Inst. R. H. 621. Citrus. Lin. Gen. Plant. 807. [so called of *Λιμῶν*, a meadow, because the leaves of this tree are of a green colour, as is likewise the fruit before it comes to maturity.] The Lemon-tree; in French, *Limonier*.

The CHARACTERS are,

The flower is composed of five oblong thick petals, which are a little concave, spreading open; these sit in a small empalement of one leaf, indented at five parts at the top. It hath about ten or twelve stamina, which are joined in three or four bodies, which are terminated by oblong summits. It hath an oval germen, supporting a cylindrical style the length of the stamina, crowned by a globular summit. The germen afterward becomes an oval fruit with a fleshy rind, inclosing a thin pulpy fruit with several cells, each having two hard seeds.

This genus of plants is ranged in the sixth section of Tournefort's twenty-first class, which includes the trees and shrubs with a Rose-shaped flower, whose pointal becomes a fleshy fruit with hard dry seeds. Dr. Linnæus has joined the Citron, Orange, and Lemon together, making them only different species of the same genus; but if we admit of the fruit being a characteristic note to distinguish the genus, the Limon cannot be joined with the Orange, for the Orange has a globular fruit, compressed at both ends, but the Limon has an oval fruit, prominent at the top, and the latter hath not so many cells as the former. It is placed in the second section of Linnæus's eighteenth class, which includes the plants whose flowers have about twenty stamina joined in several bodies.

The SPECIES are,

1. LIMON (*Vulgaris*) foliis ovato-lanceolatis acuminatis, subserratis. Limon-tree with oval, spear-shaped, acute-

pointed leaves, which are little sawed. Limon vulgaris. Ferr. Hesp. 193. The common Limon.

2. LIMON (*Spinosum*) foliis ovatis integris, ramis sub-spinosis. Limon with oval entire leaves, and branches which are somewhat spiny. Limon acris. Ferr. Hesp. 331. The sour Limon, commonly called Lime.

3. LIMON (*Racemosum*) foliis ovato-lanceolatis subserratis, fructu conglomerato. Limon with oval spear-shaped leaves, which are somewhat sawed, and fruit growing in clusters. Limon fructu racemoso. Tourn. Inst. R. H. 621. Limon with fruit growing in bunches. There are great varieties of this fruit, which are preserved in some of the Italian gardens; and in both the Indies there are several which have not yet been introduced to the European gardens; but these, like Apples and Pears, may be multiplied without end from seeds, therefore I shall only mention the most remarkable varieties which are to be found in the English gardens at present, as it would be to little purpose to enumerate all those which are mentioned in the foreign catalogues.

The Limon-tree with variegated leaves.

The sweet Limon.

The Pear-shaped Limon.

The imperial Limon.

The Limon called Adam's Apple.

The furrowed Limon.

The childing Limon.

The Limon with double flowers.

The common Limon and the sweet Limon are brought to England from Spain and Portugal in great plenty, but the fruit of the latter are not much esteemed. The Lime is not often brought to England, nor is that fruit much cultivated in Europe, but in the West-Indies it is preferred to the Limon, the juice being reckoned wholesomer, and the acid is more agreeable to the palate; there are several varieties of this fruit in the West-Indies, some of which have a sweet juice, but those are not greatly esteemed; and as the inhabitants of those islands do not propagate these fruits by grafting or budding, being contented with sowing their seeds, so there is no doubt but a great variety of them may be found by any person who is curious in distinguishing them.

As I have never known the common Limon ever vary to the Lime, when raised from seeds, nor the Lime vary to the Limon, I suppose they are specifically different, for I have frequently raised both from seeds, and have always found them continue their difference in leaf and branch, for I never waited to see their fruit, as they were only designed for stocks, to bud other sorts into them.

The Pear-shaped Limon is a small fruit with very little juice, so is not much propagated any where; the curious, who have room and convenience for keeping many of these trees, may preserve a plant or two of this sort for the sake of variety.

The fruit of the Imperial Limon is sometimes brought to England from Italy, but I do not remember to have seen any of this sort imported from Spain or Portugal, so that I suppose they are not much propagated in either of these countries; for the inhabitants of both those fine countries are so very incurious, especially in horticulture, as to trust almost entirely to nature, that the products of their gardens are inferior both in numbers and quality, to many other parts of Europe, where the climate is much less favourable for these productions. And in the article we are now upon, there are many strong instances of the slothfulness, or incuriosity of the Portuguese particularly, for they had many of the most curious sorts of Orange, Limon, and Citron-trees, brought from the Indies to Portugal formerly, which seemed to thrive almost as well there, as in their native soil, and yet they have not been propagated; there are a few trees of these sorts still remaining in some neglected gardens near Lisbon, almost unnoticed by the inhabitants. As there are also several curious trees and plants, which were formerly introduced from both Indies, some of which thrive and produce fruit amidst the wild bushes

bushes and weeds, with which those gardens are spread over.

All these sorts are propagated by budding or inarching them either on stocks of Lemons or Citrons, produced from seeds, but they will not so readily unite on Orange stocks, for which reason the Citrons are preferable to either Oranges or Lemons for stocks, as they readily join with either sort, and being of larger growth, cause the buds of the other sorts to shoot much stronger than if they were on stocks of their own kind. The method of raising these stocks, and the manner of budding them, being already exhibited under the article of AURANTIUM, it would be superfluous to repeat it here.

The culture of the Lemon being the same with that of the Orange-tree, it would be needless to repeat it here; therefore I shall only observe, that the common Lemons are somewhat harder than the Oranges, and will bring their fruit to maturity with us better than they will do, and require to have a greater share of fresh air in winter; for which reason, they should always be placed nearer to the doors or windows of the green-house; and in some curious gardens, these trees have been planted against walls, where, by covering them with glasses in winter, and protecting them from severe frost, they have produced plenty of large fruit: as these trees do generally produce stronger shoots, they require more water to be given them than the Orange; but as to the tender sorts, they must be treated with a little more care, otherwise their fruit will fall in winter, and come to nothing; these things being fully exhibited before, I refer the reader (as I hinted) to the article AURANTIUM, where their culture is fully set forth.

LIMONIUM. Tourn. Inst. R. H. 341. tab. 177. Statice. Lin. Gen. Plant. 348. [takes its name of Λιμνῶν, a marsh, as growing in marshes.] Sea Lavender.

The CHARACTERS are,

The flowers have an imbricated perianthium, rising one above another. The flower is funnel-shaped, composed of five petals, which are narrow at their base, but are broad and spreading at the top. It hath five awl-shaped stamina which are shorter than the petals, crowned by prostrate summits. It hath a small germen, supporting five slender styles, crowned by pointed stigmas. The empalement of the flower afterward becomes a capsule, shut close at the neck, but expanded above where the seeds are lodged. This genus of plants is ranged in the second section of Tournefort's eighth class, which includes the herbs with a Clove Gilliflower flower, whose pointal becomes the seed inclosed in the empalement. Dr. Linnaeus has joined this genus to the Statice of Tournefort, and places it in the fifth section of his fifth class, which contains the plants whose flowers have five stamina and five styles. As the flowers of this genus are ranged one above another in form of spikes, and those of the Statice are collected in globular heads, they may, without impropriety, be kept separate; and as there are several species of each genus, therefore I have the rather been inclined so to do, than by joining them, to swell the genus.

The SPECIES are,

1. **LIMONIUM (Vulgare)** foliis ovato-lanceolatis, caule tereti nudo paniculato. Sea Lavender with oval spear-shaped leaves, and a taper paniculated stalk. Limonium maritimum majus. C. B. P. 192. Common great Sea Lavender.
2. **LIMONIUM (Narbonense)** foliis oblongo-ovatis, caule paniculato paulo, spicis florum brevioribus. Sea Lavender with oblong oval leaves, a spreading paniculated stalk, and shorter spikes of flowers. Limonium maritimum majus alterum ferotinum Narbonense. H. R. Par. Another large late flowering Sea Lavender of Narbonne.
3. **LIMONIUM (oleosolum)** foliis ovatis obtusis, petiolis decurrentibus, caule paniculato, spicis florum erectioribus. Sea Lavender with oval obtuse leaves, running foot-stalks, a paniculated stalk, and more upright spikes of flowers. Limonium maritimum minus, oleæ folio. C. B. P. 192. Small Sea Lavender, with an Olive leaf.

4. **LIMONIUM (Humile)** foliis lanceolatis, caule humile patulo, spicis florum tenuioribus. Sea Lavender with spear-shaped leaves, a low spreading stalk, and slender spikes of flowers. Limonium Anglicum minus, caulibus ramosioribus, floribus in spicis raris sitis. Raii Hist. 217. Lesser English Sea Lavender, with more branched stalks, and flowers seldom growing in a spike.
5. **LIMONIUM (Tartaricum)** foliis lineari-lanceolatis, caule ramoso patulo, floribus distantibus uno versu dispositis. Sea Lavender with narrow spear-shaped leaves, a branching spreading stalk, and flowers placed asunder on one side the stalk. Limonium Orientale, plantaginifolio, floribus umbellatis. T. Cor. Oriental Sea Lavender with Plantain leaves, and flowers growing in an umbel.
6. **LIMONIUM (Sinuatum)** foliis radicalibus alternatim pinnato-sinuatis, caulinis ternis triquetris subulatis decurrentibus. Sea Lavender with the lower leaves alternately sinuated like wings, and those upon the stalks three-cornered, awl-shaped, and running along the foot-stalk. Limonium peregrinum, foliis asplenii. C. B. P. Foreign Sea Lavender with Spleenwort leaves.
7. **LIMONIUM (Siculum)** caule fruticoso patulo, foliis lineari lanceolatis crassis, floribus solitariis distantibus. Sea Lavender with a spreading shrubby stalk, narrow, thick, spear-shaped leaves, and flowers growing singly at a distance from each other. Limonium Siculum lignosum, gallas ferens, & non ferens. Bocc. Rar. Woody Sicilian Sea Lavender, sometimes producing galls, at other times not.
8. **LIMONIUM (Africanum)** foliis inferioribus lanceolatis hirsutis ferratis caulinis ternis linearibus acutis decurrentibus. Sea Lavender with spear-shaped lower leaves which are hairy and sawed, but growing by threes on the stalks, narrow, acute-pointed, and running along the stalk. Limonium Africanum caule alato, foliis integris hirsutis, petalo pallide flavo calyce amœnè purpureo. Martyn. Cent. 48. tab. 48. African Sea Lavender with a winged stalk, entire hairy leaves, pale yellow petals to the flower, and a beautiful purple empalement.
9. **LIMONIUM (Reticulatum)** foliis cuneiformibus, caule erecto paniculato, ramis inferioribus sterilibus nudis. Sea Lavender with wedge-shaped leaves, an upright paniculated stalk, and the under branches sterile and naked. Limonium minus flagellis tortuosis. Bocc. Mus. Small Sea Lavender with twisted shoots.
10. **LIMONIUM (Cordatum)** caule nudo paniculato, foliis spathulatis retusis. Sea Lavender with a paniculated naked stalk, and spatule-shaped blunt leaves. Limonium maritimum minus, foliolis cordatis. C. B. P. Small Sea Lavender with little leaves, which are heart-shaped.
11. **LIMONIUM (Echioideum)** caule nudo paniculato, tereti, foliis tuberculatis. Sea Lavender with a naked, taper, paniculated stalk, and leaves set with tubercles. Limonium minus annuum, bullatis foliis vel echioides. Bot. Monsp. Small annual Sea Lavender with studded leaves.
12. **LIMONIUM (Fruticosum)** caule erecto fruticoso, foliis lineari-lanceolatis obtusis, floribus alternis. Sea Lavender with an upright shrubby stalk, narrow spear-shaped leaves, ending in obtuse points, and flowers ranged alternately. Limonium Egyptiacum fruticosum, foliis lanceolatis obtusis. Shrubby Egyptian Sea Lavender with blunt spear-shaped leaves.

The first sort grows naturally in the marshes which are flowed by the sea, in several parts of England. The roots of this plant are thick, of a reddish colour, and an astringent taste, sending out many strong fibres, which strike deep in the ground; and from the upper part of the root comes out several oval spear-shaped leaves, from four to five inches long, and more than two inches broad in the middle; they are smooth, of a pretty thick consistence, and of a dark green. The stalks rise upward of a foot high, is naked of leaves, divided into many branches, which are again divided into smaller toward the top; these are terminated by slender spikes of pale blue flowers, ranged on one side the stalk above each other, coming out of narrow covers like sheaths; these appear in July, and are succeeded by oblong seeds, which are inclosed in the empalement, ripening in autumn.

The

The second sort grows naturally in the south of France on the sea-coast. The leaves of this sort are of an oblong oval form; they are six inches long, and three broad, smooth, entire, and of a deep green. The stalk rises fifteen or sixteen inches high, dividing into several spreading branches, which are divided again into smaller, and are terminated by several short spikes of pale blue flowers, ranged on one side the foot-stalk. This sort seldom flowers till the end of August, so never produces any good seeds in England.

The third sort grows naturally in Narbonne and Provence; this hath small, oval, obtuse leaves, about two inches long, and one broad, with pretty long foot-stalks, which are bordered, or winged with part of the leaves, which runs close to, and partly embrace the upper part of the root; these are of a lighter green than either of the former. The stalk rises a foot and a half high, sending out branches alternately on each side; the lower ones being long, the others gradually diminishing to the top, so as to form a loose kind of pyramid: these all point upward, and toward their ends send out spikes of pale blue flowers, which are erect. This sort flowers late in August, so never perfects seeds in England.

The fourth sort grows naturally in England. It was first discovered on the sea banks near Walton, in Essex, afterward near Malden, in the same county, and since at the mouth of the river that runs from Chichester, in Sussex. The leaves of this sort are spear-shaped, about three inches long, and one broad in the middle, lessening gradually to both ends. The stalk rises four or five inches high, dividing into many spreading branches, which are very thick set with short spikes of whitish blue flowers. These appear in August, and the seeds ripen in October.

The fifth sort was discovered by Dr. Tournefort in the Levant, from whence he sent the seeds to the Royal Garden at Paris, where they grew, and have produced seeds many years, which have been communicated to many of the curious gardens in Europe. The seeds of this sort were sent me from the Dardanelles, where the plants grow in plenty. The leaves of this sort are about four inches long, and three quarters of an inch broad in the middle, diminishing gradually to both ends. The stalks rise about five or six inches high, dividing into several spreading branches, which are again divided into smaller; these are terminated by spikes of pale blue flowers, ranged on one side the foot-stalk; the whole, when growing, being spread wide, has somewhat the appearance of an umbel of flowers. This sort flowers in August, so never ripens seeds here.

The sixth sort grows naturally in Sicily and Palestine; this is a biennial plant. The lower leaves which spread on the ground, are indented almost to the middle rib; these indentures are alternate and blunt. The stalks rise a foot and a half high, dividing upward into several branches, garnished at each joint with three narrow leaves sitting close to the stalks, from whose base proceeds a leafy membrane, or wing, which runs along on both sides the stalk; these are rough, and a little hairy. The stalks are terminated by panicles of flowers, which sit upon winged foot-stalks, each sustaining three or four flowers of a light blue colour, which continue long without fading. This sort flowers in July and August, but unless the summer is very warm and dry, the seeds do not ripen in England.

The seventh sort grows naturally in Sicily; this hath a shrubby stalk, which rises about two feet high, dividing into several ligneous branches, which spread out on every side; the lower part of these are closely garnished with gray leaves, like those of the Sea Purslain, and are of a thick consistence. The branches are terminated by panicles of blue flowers, having one funnel-shaped petal, which come out singly at a distance from each other, having long tubes, but divide into five segments upward, which spread open. This flowers from June till autumn, but never pro-

duces seeds in England: there is a variety of this, which bears galls like those upon the Oak, which grows naturally in Sicily, but I do not know if it is a different species, for those plants which are in the English gardens have no appearance of any.

The eighth sort was raised in the Chelsea garden, from seeds which were brought me from Africa; this is a biennial plant, which dies soon after it has produced flowers and seeds. The lower leaves are but few in number; they are spear-shaped, hairy, and slightly sawed on their edges, about two inches long, and half an inch broad. The stalk rises about fifteen inches high, which at each joint is garnished with three narrow leaves, ending in acute points; from the base of these leaves is continued a leafy membrane, or wing, running along the stalk on each side; these stalks branch out but little, and are terminated by short panicles of flowers, whose foot-stalks are not winged as in the former; each foot-stalk sustains two or three flowers of a bright blue colour, out of the middle of which arises another small flower of a pale yellow colour. This sort flowered in July and August, 1757, but did not ripen seeds.

The ninth sort grows naturally in Sicily, and was found growing on the border of the sea in Norfolk, by Mr. Henry Scott, a gardener, and has since been found in plenty in Lincolnshire, by — Banks, Esq; The lower leaves of this sort are narrow at their base, but enlarge upward, where they are broad, and rounded at the top, in shape of a wedge. The stalks are slender and stiff, rising from seven to fourteen inches high, sending out many slender side branches; all those which proceed from the lower part of the stalk are barren, having no flowers; but toward the top they have short panicles of whitish flowers, which are small, and sit three or four together upon one foot-stalk. This sort flowers in July and August.

The tenth sort grows naturally near the sea, about Marseilles and Leghorn; this hath many thick fleshy leaves, which are shaped like a spatula, growing near the root, and spread on the ground; they are smooth, and of a grayish colour. The stalks are naked, and rise about six inches high, dividing toward the top into many smaller branches, which are terminated by short crooked panicles of small flowers, of a pale red colour. This sort flowers in August, but never produces seeds in this country.

The eleventh sort grows naturally about Montpellier and in Italy; this is an annual plant; with long narrow leaves, which are set with rough tubercles like the leaves of Viper's Bugloss. The stalks rise about eight inches high, dividing into two or three small branches, which are terminated by reflexed short spikes of pale blue flowers; these come out late in August, and the seeds are seldom perfected in England.

The twelfth sort grows naturally in Egypt, from whence the seeds were sent to the Royal Garden at Paris, part of which were sent me by Dr. Bernard de Jussieu, which grew in the Chelsea garden, where there are several plants, which have produced flowers many years. This rises with an upright shrubby stalk to the height of eight or ten feet, divided upward into many branches, garnished with narrow spear-shaped leaves, placed without order; they are of a thick consistence, and of a gray colour, sitting close to the branches. The flowers are produced at the end of the branches in loose panicles, standing alternate on each side the stalk, one above another, with intervals between them; they have pretty long tubes, which enlarge upward, where they are cut into five obtuse segments, which spread open; these are of a bright sky blue, but fade to a purple before they fall off. The flowers begin to appear in July, and there is a succession of them till winter.

The first, second, third, fourth, fifth, and eighth sorts, are abiding plants, which will thrive in the open air in England; such of these as grow naturally in England, may be easily procured from the places where they grow; these plants may be transplanted at almost any time of the year, provided they are carefully

carefully taken up, preserving some earth to their roots, and in hot weather to shade them till they have taken new root; after which time they will require no other culture but to keep the ground clean from weeds, and in the spring to stir up the ground between them to loosen it. As these plants do not require much culture, nor do they take up much room, so a few of each sort may be allowed to have a place in gardens, where there is room, for the sake of variety. These plants do not propagate very fast in gardens, so the roots need not be removed oftener than every third or fourth year, at which time they may be slipped to increase them; the best time for this is in the autumn, that the plants may be well rooted before the spring, otherwise they will not flower very strong the following summer. They should be planted in a loamy soil, on an east aspect border, where they may enjoy the morning sun; but screened from the great heat in the middle of the day; in such a situation the roots will continue several years, and flower as well as in their native soil.

These plants may also be propagated by seeds, so that such of them as do not grow naturally in England, may be obtained by procuring their seeds from abroad. These should be sown upon a border exposed to the morning sun, and on a soft loamy soil, early in the spring, for the seeds lie a considerable time in the ground before the plant comes up; therefore the ground must be kept entirely clean from weeds, and if the season should prove very dry, the border should be watered two or three times a week, otherwise the seeds will lie a whole year before they vegetate; when the plants come up, they must be kept clean from weeds, and in very dry weather watered, and in the autumn they may be transplanted where they are designed to remain.

The sixth and eighth sorts are biennial plants, which rarely perfect their seeds in England, so that unless fresh seeds can be procured from warm countries, where they ripen well, it will be very difficult to continue the sorts. If the seeds of these can be obtained time enough to sow them in the autumn, the plants will come up the following spring; but when they are sown in the spring, they seldom grow the same year. These seeds should be sown on a border of loamy earth, not stiff or moist, and exposed to the south; but when the sun is warm, the border should be shaded with mats, to prevent the earth from drying too fast. When the plants come up, they must be kept clean from weeds; and if they are too close, some of them should be carefully taken out as soon as they are fit to remove, and planted in small pots, placing them in the shade till they have taken new root; then they may be placed where they may enjoy the morning sun till autumn, when they should be put into a hot-bed frame, where they may be screened from hard frost, but enjoy the free air in mild weather; and those plants which are left in the border where they were sown, must be covered with mats in hard frost; for though they will often live through the winter in mild seasons, yet hard frost will always destroy them. The following summer the plants will flower, and if the season proves warm and dry, they will ripen seeds, and the roots soon after decay.

The seventh and twelfth sorts are shrubby plants, which are too tender to live through the winter in the open air in England, so the plants must be removed into shelter in the autumn, but they only require protection from hard frost: these plants may be placed with Myrtles, Oleanders, and other hardy green-house plants, where they often continue to flower great part of winter, and make a pretty variety. These sorts are easily propagated by cuttings, which, if planted in July on a shady border, and duly watered, will take root in six or seven weeks, when they should be taken up and planted into pots filled with light loamy earth, placing them in the shade till they have taken root; then they may be exposed till Oc-

tober, at which time they must be removed into shelter.

The eleventh sort is annual, and rarely ripens seeds here, so these must be procured from abroad, and sowed in the same way as the sixth and eighth sorts.

LINARIA. Tourn. Inst. R. H. 168. tab. 76. Antirrhinum. Lin. Gen. Plant. 668. [so called of Linum, Lat. flax, because its leaves resemble flax.] Toad-flax; in French, *Linaire*.

The CHARACTERS are,

The flower hath a permanent empalement of one leaf, divided into five parts almost to the bottom. The flower hath one petal, and is of the ringent (or grinning) kind, with an oblong swelling tube, having two lips above, with the chaps shut. The upper lip is bifid and reflexed on the sides, the lower lip is trifid and obtuse. It hath an oblong nectarium, which is awl-shaped and prominent behind, and four stamina, which are included in the upper lip, two of which are shorter than the other, and a roundish germen supporting a single style, crowned by an obtuse stigma. The germen afterward turns to a roundish obtuse capsule with two cells, filled with small seeds.

This genus of plants is ranged in the fourth section of Tournefort's third class, which includes the herbs with a tubulous, anomalous, personated flower, of one petal. Dr. Linnæus joins this genus, and also the Asarina of Tournefort to the Antirrhinum, and places that genus in the second section of his fourteenth class, in which are contained the plants whose flowers have two long and two short stamina, and the seeds are included in a capsule. The plants of this genus agree in their general characters with those of the Antirrhinum, or Calve's Snout, except in one particular, which is in the nectarium of the Linaria, which, from the base of the petal, stretches out like a heel; whereas the flowers of the Antirrhinum, have their nectarium lodged within the base of the petal: this being so very obvious, and both genera having many species, I thought it might be easier for students in botany to range them under different genera, than to join them under one.

The SPECIES are,

1. **LINARIA** (*Vulgaris*) foliis lanceolato-linearibus confertis caule erecto, spicis terminalibus sessilibus. *Toad-flax with spear-shaped linear leaves growing in clusters, and an upright stalk terminated by spikes of flowers, sitting close to the stalk. Linaria vulgaris lutea, flore majore. C. B. P. 212. Common yellow Toad-flax with a larger flower.*
2. **LINARIA** (*Triphylla*) foliis ternis ovatis. *Toad-flax with oval leaves placed by threes. Linaria triphylla minor lutea. C. B. P. 212. Smaller three-leaved yellow Toad-flax.*
3. **LINARIA** (*Lusitanica*) foliis quaternis lanceolatis, caule erecto ramoso, floribus pedunculatis. *Toad-flax with spear-shaped leaves placed by fours, an upright branching stalk, and flowers upon foot-stalks. Linaria latissimo folio Lusitanica. H. R. Par. Broadest-leaved Portugal Toad-flax.*
4. **LINARIA** (*Alpina*) foliis subquaternis linearibus caule diffuso, floribus racemosis. *Toad-flax with linear leaves placed by fours on the lower part of the stalk, a diffused stalk and branching flowers. Linaria quadrifolia supina. C. B. P. 213. Low four-leaved Toad-flax.*
5. **LINARIA** (*Purpurea*) foliis lanceolato-linearibus sparsis, caule florifero erecto spicato. *Toad-flax with spear-shaped linear leaves, and the flower-stalks erect and spiked. Linaria purpurea major odorata. C. B. P. 213. Greater sweet-scented purple Toad-flax.*
6. **LINARIA** (*Repens*) foliis linearibus confertis, caule erecto ramoso, floribus spicatis terminalibus. *Toad-flax with linear leaves in clusters, an erect branching stalk, and flowers in spikes terminating the stalks. Linaria creulea, foliis brevioribus & angustioribus. Raii Syn. 3. 282. Blue Toad-flax with shorter and narrower leaves.*
7. **LINARIA** (*Multicaulis*) foliis inferioribus quinis linearibus. *Toad-flax with linear leaves, placed by fives at the lower part of the stalks. Linaria Sicula multicaulis, folio molluginis. Bocc. Rar. 38. Sicilian Toad-flax with many stalks and a Bedstraw leaf.*

8. LINARIA (*Tristis*) foliis lanceolatis sparsis, inferioribus oppositis, nectariis subulatis, floribus subsessilibus. *Toad-flax with spear-shaped sparsed leaves, which on the lower part of the stalk are opposite, awl-shaped nectariums, and flowers sitting almost close.* Linaria Hispanica procumbens, foliis uncialibus glaucis, flore flavescente pulchrè striato, labiis nigro-purpureis. Act. Phil. N° 412. *Trailing Spanish Toad-flax with gray leaves an inch long, yellow flowers beautifully striped, and dark purple lips.*
9. LINARIA (*Monspesulana*) foliis linearibus confertis, caule nitido paniculato, pedunculis spicatis nudis. *Toad-flax with linear leaves in clusters, a paniculated stalk, and flowers in spikes on naked foot-stalks.* Linaria capillaceo folio, odora. C. B. P. 213. *Sweet Toad-flax with hair-like leaves.*
10. LINARIA (*Villosa*) foliis lanceolatis hirtis alternis, floribus spicatis, foliolo calycino supremo maximo. *Toad-flax with alternate, hairy, spear-shaped leaves, flowers in spikes, and the upper leaf of the empalement very large.* Linaria latifolia villosa, laciniis calycinis inæqualibus, flore majore pallido striato rictu aureo. Horteg. Icon. *Broad-leaved hairy Toad-flax, whose empalement is unequally cut, and a large pale striped flower with a golden snout.*
11. LINARIA (*Pelisseriana*) foliis caulinis linearibus sparsis, radicalibus rotundis. *Toad-flax with linear leaves placed sparsedly on the stalks, and on the lower leaves round.* Linaria annua purpureo violacea, calcaribus longis, foliis imis rotundioribus. Vaill. Bot. Par. 118. *Annual purple Violet Toad-flax, with long spurs and rounder leaves at bottom.*
12. LINARIA (*Chalepensis*) foliis lineari-lanceolatis alternis, floribus racemosis, calycibus corollâ longioribus. *Toad-flax with linear spear-shaped leaves placed alternate, branching flowers, and empalements longer than the petals.* Linaria annua angustifolia, flosculis albis, longius caudatis. Triump. 87. *Narrow-leaved annual Toad-flax, with white flowers having long tails.*
13. LINARIA (*Dalmatica*) foliis lanceolatis alternis, caule suffruticoso. *Toad-flax with spear-shaped alternate leaves, and an under shrub stalk.* Linaria latifolia Dalmatica, magno flore. C. B. P. 212. *Broad-leaved Toad-flax of Dalmatia with a large flower.*
14. LINARIA (*Genistifolia*) foliis lanceolatis acuminatis, paniculâ virgatâ. *Toad-flax with spear-shaped acute-pointed leaves, and a rod-like panicle.* Linaria genistæ folio glauco, flore luteo. Par. Bat. App. 9. *Toad-flax with a gray Dyer's Weed leaf and a yellow flower.*
15. LINARIA (*Spuria*) foliis ovatis alternis, caule flaccido procumbente. *Toad-flax with oval leaves placed alternate, and a weak trailing stalk.* Elatine folio subrotundo. C. B. P. 253. *Fluellin with a roundish leaf.*
16. LINARIA (*Elatina*) foliis hastatis alternis, caule flaccido procumbente. *Toad-flax with arrow-pointed leaves placed alternate, and a weak trailing stalk.* Elatine folio acuminato. C. B. P. 253. *Fluellin with an acute-pointed leaf.*
17. LINARIA (*Cymbalaria*) foliis cordatis quinquelobatis alternis glabris. *Toad-flax with heart-shaped leaves having five lobes, which are alternate and smooth.* Linaria hederaceo folio glabro, seu Cymbalaria vulgaris. Tourn. Inst. R. H. 169. *Toad-flax with a smooth Ivy leaf, or common Cymbalaria.*

There are several other species of this genus which are well known and described, which are of less note, so are very rarely admitted into gardens, for which reason I have not enumerated them here.

The first of these plants grows in great plenty upon the sides of dry banks in most parts of England, and is seldom cultivated in gardens; for it is a very troublesome plant to keep within bounds, the roots being very apt to spread under ground, and rise at a great distance from the mother plant, whereby it greatly injures whatever plants stand near it. This is one of the plants mentioned in the catalogue of simples at the end of the College Dispensatory, to be used in medicine.

This hath a great number of slender white roots, which creep far on every side, from which arise se-

veral erect branching stalks a foot and a half high, garnished with narrow gray leaves in clusters, and terminated by spikes of yellow flowers, sitting close to the stalk. The flowers are of one petal, with a long tube, to which is fixed a spur or heel, called a nectarium; the fore parts of the flower has the appearance of the mouth of an animal, the under lip is hairy within; the chaps are of a golden colour, but the other parts of the flower are of a pale yellow; these are succeeded by roundish capsules with two cells, filled with flat black seeds. It flowers in July and August, when it makes a pretty appearance, so that a few plants might be allowed a place in gardens, were it not for their creeping roots, which spread too much, and become troublesome weeds; therefore the roots should be confined in pots to keep them within bounds.

There is an ointment made of this herb and hog's-lard, which is accounted excellent for the piles, being mixed with the yolk of an egg at the time of using it. The plant is reckoned to be aperitive and diuretic, opening obstructions of the liver and spleen, helping the dropsy and jaundice.

The second sort grows naturally about Valencia and in Sicily; this is an annual plant, which rises with an upright branching stalk near a foot and a half high, garnished with oval, smooth, gray leaves, placed often by threes, and sometimes by pairs opposite at the joints; the flowers grow in short spikes at the top of the stalks; they are shaped like those of the common sort, but have not so long tubes; they are yellow, with Saffron-coloured chaps. This sort flowers in July and August, and the seeds ripen in the autumn, and the plants soon after decay.

There is a variety of this whose flowers have a purple standard and spur, which makes a pretty appearance in a garden; but it is generally supposed to be only an accidental variety which has risen from seeds of the former, for which reason I have not enumerated it here; though from many years culture of both sorts, I have never yet perceived either of them alter. The leaves of this are longer than those of the yellow, but in other respects they do not differ.

This sort may be propagated by seeds, or by the roots; the seeds should be sown in the spring, on the borders of the flower-garden where they are designed to remain; and when the plants come up, they should be thinned where they are too close, and kept clean from weeds, which is all the culture they require. If some of the seeds are sown in autumn upon a warm dry border, the plants will live through the winter, unless the frost proves very severe; and these autumnal plants will grow larger, flower earlier, and from these good seeds may always be obtained: the first sort is seldom admitted into gardens.

The third sort rises with upright stalks near two feet high, which are garnished with spear-shaped smooth leaves, placed sometimes by fours round the stalk, and at others by pairs opposite; the stalks are terminated by large purple flowers with long spurs, standing upon foot-stalks. This flowers in July, but seldom ripens seeds in England; it grows naturally in Portugal and Spain.

This sort is tenderer than the last, so should be planted in a dry soil and a warm situation, otherwise the plants are often destroyed in winter. This plant is propagated by seeds in the same manner as the former, as also by parting the roots; but it is adviseable always to keep some of these plants in pots, that they may be removed into shelter in winter, otherwise in hard frosts they will be killed.

The fourth sort grows naturally about Verona, from whence I received the seeds. This is a perennial plant, from whose roots arise several diffused stalks about eight inches long, garnished with narrow, short, gray leaves, placed by fours round the stalks at bottom, but upward they are opposite; the stalks are terminated by short branching tufts of pale yellow flowers with golden chaps. This sort flowers in June, and in warm seasons sometimes the seeds will ripen here in the autumn.

The fifth sort grows naturally in the south of France and Italy; this hath a perennial root, sending out many stalks; those of them which support the flowers are erect, and near three feet high, but the other stalks are weaker, and hang loosely on every side the plants; these are garnished with long, narrow, spear-shaped leaves placed sparsely; they are smooth, and of a gray colour. The stalks are terminated by long loose spikes of blue flowers, which appear in June, July, and August, and the seeds ripen in the autumn, which, if permitted to scatter, will produce plenty of young plants without any further care.

The sixth sort grows naturally about Henley in Oxfordshire, and also in some parts of Hertfordshire. This hath a perennial root, from which arise several stalks near two feet high, which branch out on every side, and are garnished with narrow leaves growing in clusters toward the bottom, but upward they are sometimes by pairs, and at others single. The flowers are produced in loose spikes at the end of the stalks; they are of a pale blue colour, which appear in June and July, and the seeds ripen in the autumn; which, if permitted to scatter, will produce plenty of plants. When the seeds happen to fall upon old walls, the plants will grow there and continue longer than those planted in the ground.

I received a specimen of this sort from abroad, by the title of *Linaria arvensis cærulea*. C. B. P.

The seventh sort grows naturally in Sicily; this is an annual plant, from whose root arises many stalks which are very slender and about a foot high, which on their lower part are garnished with five very narrow leaves at each joint, but upward they are sometimes by pairs, and at others they are single: the stalks are divided into many small branches, which are garnished with small yellow flowers, coming out single at distances from each other; these are shaped like those of the other species. The flowers appear in July, and the seeds ripen in the autumn. There are two varieties of this, one with a deep yellow, and the other a sulphur-coloured flower.

This is propagated by seeds in the same manner as the second sort; if the seeds are permitted to scatter, the plants will come up without care, and if they are kept clean from weeds, will produce their flowers early in the summer.

The eighth sort grows naturally on the rocks about Gibraltar, from whence the late Sir Charles Wager brought the seeds, which were sown in his curious garden at Parson's Green near Fulham, where they succeeded, and from thence many curious gardens were furnished with the plants. This has a perennial root, from which come out many slender succulent stalks about eight or nine inches long, which are weak and hang down on every side the root; they are garnished with short, narrow, spear-shaped leaves, of a gray colour, and succulent, standing without order; they are about one inch long, and a fifth part of an inch broad. The flowers are produced at the end of the stalks in small bunches; they are yellow, marked with purple stripes, and the chaps of the flower, as also the spur, are of a dark purple colour; the flowers sit close upon the top of the stalk. They appear in June and July, but do not produce seeds in England.

This plant is easily propagated by planting cuttings in any of the summer months, which, if watered and shaded, will soon take root, and may be afterwards planted in pots, filled with fresh, light, undunged earth, in which they will succeed much better than in a richer soil; for if they are planted in a fine rich earth, it, causes them to grow very fast for a short time, but they seldom fail to rot soon after. These must be removed into shelter in winter; where they must have as much free air as possible in mild weather, and be only protected from severe cold; so that if the pots are placed under a hot-bed frame, the plants will succeed better than in a green-house, where they are apt to draw too much, which will cause them to decay.

The ninth sort grows naturally in Wales, particularly

near Penryn. This hath a perennial root, from which arise many branching stalks near two feet high, garnished with very narrow leaves growing in clusters, which are of a grayish colour. The flowers are produced in loose spikes at the end of the branches; they are of a pale blue colour, and smell sweet. These appear in June, and there is often a succession of flowers on the plants till winter. The seeds ripen in the autumn, which, if permitted to scatter, will furnish a supply of young plants without any further care. If the seeds of this sort get on a wall, the plants will come up, and continue there a much longer time than when they are planted in the ground.

The tenth sort grows naturally in Spain; the seeds of it were sent me by Dr. Hortega from Madrid. This is an annual plant, which rises with a single stalk about a foot and a half high, garnished with hairy spear-shaped leaves, sitting close to the stalk, which are placed alternate. The flowers grow on the top of the stalks in loose spikes; they are of a pale yellow colour, with a few dark stripes, and the chaps are of a gold colour; the upper segment of the empalement is much larger than the lower. The flowers of this sort are as large as those of the common sort; they appear in July, and the seeds will in warm seasons ripen in autumn in England.

The seeds of this sort should be sown in the spring, upon a border of light earth where the plants are designed to remain; and when the plants come up, they must be treated in the same way as those of the second sort.

The eleventh sort grows naturally in France; this is an annual plant, having round leaves at the root; the stalks are slender, branching, and rise a foot high, garnished with very narrow leaves at each joint. The flowers are produced in loose spikes at the end of the branches; they are of a bright blue colour, and appear in July; the seeds ripen in the autumn, at which time they should be sown; for those which are sown in the spring frequently lie in the ground till the spring following, before the plants appear. When the plants come up, they must be thinned where they are too close, and kept clean from weeds, which is all the culture they require.

The twelfth sort grows naturally in Sicily; this is an annual plant, which rises with a branching stalk two feet high, garnished with very narrow spear-shaped leaves placed alternately. The flowers are produced singly all along the branches the greatest part of their length; they are small, white, and have very long tails or spurs. This flowers in July, and the seeds ripen in the autumn. If the seeds of this sort are permitted to scatter, the plants will come up and succeed better than if sown with care, and require no other culture but to keep them clean from weeds.

The thirteenth sort grows naturally in Crete, and also in Dalmatia. This rises with a strong ligneous stalk three feet high, garnished with smooth spear-shaped leaves placed alternate, sitting close to the stalk. The flowers are produced at the end of the branches in short loose spikes; they are of a deep yellow colour, and much larger than those of the common sort, standing upon short foot-stalks. This sort flowers in July, but the seeds very rarely ripen in England, so that the plants are seldom seen in any gardens here. It is propagated by seeds, which should be sown early in the spring upon a border of light earth; and when the plants come up and are fit to remove, some of them should be planted in pots filled with light sandy earth, and placed in the shade till they have taken new root; then they may be exposed with other hardy exotic plants till the end of October, when they should be put into a common hot-bed frame, where they may be protected from hard frost; but in mild weather they should enjoy the free air, for these plants only require to be protected from hard frost, for in mild winters they will live abroad without shelter, if they are upon a dry soil; therefore a part of the plants may be planted on a warm border of poor sandy soil, where they will live through our common winters very

very well; and those plants which grow in rubbish and are stunted, will endure much more cold than the others.

The fourteenth sort grows naturally in Siberia; this is a biennial plant, which rises with an upright branching stalk from three to four feet high, garnished with spear-shaped leaves, ending in acute points, of a grayish colour; these are placed alternate. The flowers are produced at the end of the branches, in loose panicles; they are of a bright yellow colour, and shaped like those of the other sorts. This flowers in June and July, and the seeds ripen in the autumn, which, if permitted to scatter, the plants will come up the following spring, and require no other care but to thin them where they are too close, and keep them clear from weeds. The plants always decay after they have ripened their seeds, therefore there should be a supply of young ones annually raised.

The fifteenth sort grows naturally amongst Wheat and Rye, in several parts of England. It is an annual plant with weak trailing stalks, which spread on the ground, and are a foot and a half long; they are hairy, and garnished with oval leaves, placed alternately; from the setting on of the foot-stalks of the leaves; at each joint comes out one flower, shaped like those of the other species. The upper lip is yellow, and the under is purple; these appear in June and July, and the seeds ripen in autumn, which should be then sown, or permitted to scatter; for if it is sown in the spring, it seldom grows the same year, for it is rarely seen among spring-sown Corn, in those lands where it commonly grows.

This plant is used in medicine, and is esteemed vulnerary, and good for old cancerous sores and ulcers; it is accounted good for hæmorrhages of all sorts.

The sixteenth sort differs from the fifteenth, in nothing but the shape of the leaves, which in this are shaped like the point of an arrow, and those of the other are oval; this is more commonly found in England than the other.

The seventeenth sort was brought from Italy to England, where it now grows in as great plenty in the neighbourhood of London, as if it was in its native country, growing from the joints of walls, wherever the seeds happen to scatter. It is a perennial plant, which will thrive in any soil or situation, so that where it is once established, it will be difficult to root out, for the seeds will get into any joints of walls, or the decayed parts of pales, as also in the hollow of trees, where they grow and propagate plentifully; for the stalks put out roots at their joints, so spread themselves to a great distance. It flowers all the summer, and the seeds ripen in succession. It is never cultivated in gardens, but is supposed to be an excellent wound herb.

LINGUA CERVINA. Hart's Tongue.

These plants commonly grow out from the joints of old walls and buildings, where they are moist and shady, and also upon shady moist banks, but are seldom cultivated in gardens. There is a very great variety of these plants, both in the East and West-Indies, but there are very few species of them in Europe; all the hardy sorts may be propagated by parting their roots, and should have a moist soil and shady situation.

LINUM. Tourn. Inst. R. H. 339. tab. 170. Lin. Gen. Plant. 349. Flax; in French, *Lin*.

The CHARACTERS are,

The flower hath a permanent empalement, composed of five small, spear-shaped, acute leaves. It is composed of five large oblong petals, which are narrow at their base, but broader upward, and spread open. It hath five awl-shaped erect stamina, terminated by arrow-shaped summits. In the center is situated an oval germen, supporting five slender styles, crowned by reflexed stigmas. The germen afterward turns to a globular capsule with ten cells, opening with five valves; in each cell is lodged one oval, plain, smooth seed, with an acute point.

This genus of plants is ranged in the fifth section of Linnæus's fifth class, intitled Pentandria Pentagynia,

which contains those plants whose flowers have five stamina and five styles.

The SPECIES are,

1. LINUM (*Ustatissimum*) calycibus capsulisque mucronatis petalis crenatis, foliis lanceolatis alternis caule subsolitario. Lin. Sp. Plant. 277. *Flax with empalements, and capsules ending in acute points, crenated petals to the flower, spear-shaped alternate leaves, and the stalks commonly single.* Linum sativum. C. B. P. 214. *Matured Flax.*
2. LINUM (*Humile*) calycibus capsulisque mucronatis, petalis emarginatis, foliis lanceolatis alternis, caule ramoso. *Flax with sharp-pointed empalements and capsules, the petals of the flower indented, spear-shaped alternate leaves, and a branching stalk.* Linum sativum humilius flore majore. Bobart. Boerh. Ind. alt. 1. p. 284. *Low matured Flax with a larger flower.*
3. LINUM (*Narbonense*) calycibus acuminatis, foliis lanceolatis sparsis strictis scabris acuminatis, caule tereti basi ramoso. Lin. Sp. Plant. 278. *Flax with acute-pointed empalements, rough spear-shaped leaves placed without order, ending in acute points, and a taper stalk branching at the base.* Linum sylvestre, cæruleum, folio acuto. C. B. P. 107. *Wild blue Flax with an acute leaf.*
4. LINUM (*Tenuifolium*) calycibus acuminatis, foliis sparsis linearibus setaceis retrorsum scabris. Lin. Sp. Plant. 278. *Flax with acute-pointed empalements, and narrow bristly leaves placed without order, which are rough on their outside.* Linum sylvestre angustifolium, floribus dilute purpurascens vel carneis. C. B. P. 214. *Narrow-leaved wild Flax, with a pale purplish or flesh-coloured flower.*
5. LINUM (*Anglicum*) calycibus capsulisque acuminatis, caule subnudo scabro, foliis acuminatis. *Flax with acute-pointed empalements, an almost naked rough stalk, and acute-pointed leaves.* Linum perenne, majus, cæruleum, capitulo majore. Mor. Hist. 2. 573. *Greater blue perennial Flax with larger beads.*
6. LINUM (*Perenne*) calycibus capsulisque obtusis, foliis alternis lanceolatis acutis, caulibus ramosissimis. Plat. 166. *Flax with obtuse empalements and capsules, alternate, spear-shaped, acute leaves, and very branching stalks, commonly called Siberian perennial Flax.*
7. LINUM (*Hispanicum*) calycibus acutis, foliis linearilanceolatis sparsis, caule paniculato procumbente. *Flax with acute empalements, linear spear-shaped leaves placed without order, and a paniculated stalk.*
8. LINUM (*Bienne*) calycibus patulis acuminatis, foliis linearibus alternis, caule ramoso. *Flax with spreading acute-pointed empalements, linear alternate leaves, and a branching stalk.*
9. LINUM (*Hirsutum*) calycibus hirsutis acuminatis sessilibus alternis, caule corymboso. Lin. Sp. Plant. 277. *Flax with hairy acute-pointed empalements, placed alternate close to the stalks, whose flowers are formed in a corymbus.* Linum sylvestre, latifolium, hirsutum cæruleum. C. B. P. 339. *Broad-leaved, hairy, wild Flax, with a blue flower.*
10. LINUM (*Strictum*) calycibus foliisque lanceolatis strictis mucronatis, margine scabris. Lin. Sp. Plant. 279. *Flax with spear-shaped leaves, and empalements which end in acute points, and have rough edges.* Passerina Lobelii. J. B. 3. p. 454.
11. LINUM (*Fruticosum*) calycibus acutis, petalis integris, foliis inferioribus linearibus fasciculatis, superioribus alternis, caule suffruticoso. *Flax with acute empalements, entire petals to the flower, linear under leaves growing in clusters, the upper ones alternate, and a shrubby stalk.* Linum sylvestre acutis foliis fruticans. Barrel. Icon. 1008. *Wild Flax with a shrubby stalk and acute leaves.*
12. LINUM (*Nodiflorum*) foliis lanceolatis alternis, floribus alternis sessilibus caule simplici. *Flax with spear-shaped leaves placed alternate, flowers growing alternate, and close to the stalks, which are single.* Linum luteum ad singula genicula floridum. C. B. P. 214. *Yellow Flax with single flowers growing from the joints.*

13. LINUM (*Catharticum*) foliis oppositis ovato-lanceolatis, caule dichotomo, corollis acutis. Hort. Cliff. 372. *Flax with spear-shaped leaves placed opposite, a stalk divided by pairs, and acute petals to the flower.* Linum pratense, flosculis exiguis. C. B. P. 214. *Meadow Flax with small flowers, commonly called Mountain Flax.*

14. LINUM (*Maritimum*) calycibus ovatis acutis muticis, foliis lanceolatis inferioribus oppositis. Lin. Sp. Plant. 280. *Flax with oval, acute, chaffy empalements, and spear-shaped leaves, the lower of which grow opposite.* Linum maritimum luteum. C. B. P. 214. *Yellow maritime Flax.*

The first sort is the Flax which is cultivated in most parts of Europe, but particularly in the northern parts; this is an annual plant, which usually rises with a slender unbranched stalk a foot and a half high, garnished with narrow spear-shaped leaves placed alternate, ending in acute points, and are of a gray colour. The flowers are produced on the top of the stalks, each stalk sustaining four or five blue flowers, composed of five petals, which are narrow at their base, but broad at the top, where they are slightly crenated. The empalement of the flower is cut into five parts, which end in acute points. The flowers appear in June, and are succeeded by roundish capsules which have ten cells, opening with five valves, which are terminated by acute points; each cell contains one smooth flattish seed, ending in a point, of a brownish colour. The seeds ripen in September, and the plants soon after perish.

When this plant is cultivated in the fields after the usual method, it seldom rises higher than is before mentioned; nor do the stalks branch out, but when they are allowed more room, they will rise more than two feet high, and put out two or three side branches toward the top, especially if the soil is pretty good where it is sown.

The second sort differs from the first, in having stronger and shorter stalks branching out much more. The leaves are broader, the flowers are larger, and the petals are indented at their extremities. The seed-vessels are also much larger, and the foot-stalks are longer; these differences are lasting, for I have cultivated this and the common Flax on the same ground upward of thirty years, and have never found either of them alter.

The third sort grows naturally in the south of France, in Italy, and Spain; this rises from a foot to eighteen inches high, branching out almost to the bottom into many long slender branches, which are garnished with narrow, spear-shaped, acute-pointed leaves, placed without order; these are rough to the touch. The flowers are produced at the end of the branches, almost in form of an umbel; they are smaller than those of the manured sort, and are of a pale blue colour. The seed-vessels are much smaller, and not so round. It flowers and seeds about the same time as the former.

The fourth sort grows naturally about Vienna and in Hungary; this sort seldom rises more than a foot high, with a slender stalk, which divides into three or four slender naked foot-stalks at the top, each sustaining two or three flowers, which are of a pale blue colour. The stalks are garnished with short, narrow, bristly leaves, standing erect, which are rough on their outside. This flowers and seeds about the same time as the former, and the plant soon after decays.

There are two or three varieties of this, which differ in the colour of their flowers, but in other respects are the same.

The fifth sort grows naturally in some parts of England, particularly in Cambridgeshire; this hath a perennial root, from which arise three or four inclining stalks, garnished with short narrow leaves toward their base, but upward have scarce any. The flowers are produced at the end of the stalks, sitting very close; they are of a blue colour, and about the size of those of the manured kind, and are succeeded

by pretty large round seed-vessels, ending in acute points. This flowers about the same time as the common Flax, but the roots will continue four or five years.

The sixth sort grows naturally in Siberia; it hath a perennial root, from which arise several strong stalks, in number proportional to the size of the root, and in height according to the goodness of the soil where it grows; for in rich moist ground they will rise near five feet high, but in middling ground about three feet; these divide into several branches upward, and are garnished with narrow spear-shaped leaves, placed alternate; they are not much more than an inch long, and an eighth of an inch broad, of a deep green, ending in acute points. The flowers are produced at the end of the branches, forming a kind of umbel, the stalks rising nearly of the same height. The flowers are large, and of a fine blue colour; these appear in June, and are succeeded by obtuse seed-vessels, which ripen in September.

The seventh sort grows naturally in Spain, from whence I received the seeds; this hath a perennial root, from whence come out several trailing stalks, which are closely garnished with leaves; these never rise much from the ground, but between these come out upright stalks, which rise upward of two feet high, garnished with pretty long, narrow, spear-shaped leaves, placed without order. The flowers grow in a sort of panicle toward the upper part of the branches; they are about the size of those of the common sort, and are of the same colour. It flowers and ripens its seeds about the same time, and the roots continue several years.

The eighth sort I received from Istria; this hath a biennial root, from which arise two or three stalks, which divide into several branches, at about six inches from the root, which divide again into smaller toward the top; they are garnished with short, narrow, acute-pointed leaves, placed alternately. The flowers come out from the side of the branches, standing upon long foot-stalks. The empalement of the flower is composed of five broadish leaves ending in acute points, which spread open; the flowers are of the same size and colour as the common Flax, and appear at the same season. The seeds ripen in the autumn, and the roots abide several years.

The ninth sort grows naturally in Hungary and Austria; this hath a perennial root, from which arise several stalks near two feet high, which are thick, firm, and hairy, dividing at the top into several branches, and are garnished with broader leaves than the other species, which are hairy. The flowers grow along the stalks alternately; they are large, and of a deep blue colour, appearing at the same time with the common sort, and the seeds ripen in the autumn.

The tenth sort grows naturally in Germany and the south of France, amongst the Corn. This is an annual plant, rising with an upright stalk near a foot and a half high, garnished with spear-shaped acute-pointed leaves, which are rough on their edges; they are about the same length of those of the common Flax, but a little broader, placed alternately. The stalks divide toward the top into several branches, each sustaining two or three yellow flowers, sitting in spear-shaped acute-pointed empalements. These appear in July, but unless the autumn proves favourable, the seeds never ripen in England.

The eleventh sort grows naturally in Spain; the seeds of it were sent me from Madrid by Dr. Hortega. This hath a shrubby stalk which rises a foot high, sending out several branches which are garnished with very narrow leaves coming out in clusters; but the flowering branches are garnished with broader and longer leaves, placed alternately at every joint. The flowers are produced at the end of the branches, standing erect upon long slender foot-stalks; they have acute-pointed empalements. The petals of the flower are large, entire, and white, but before the flowers open, they are of a pale yellow colour. These flowers appear in July,

but unless the autumn proves favourable, the seeds do not ripen in England. The flower-stalks of this sort decay in the autumn, but the lower shrubby stalk continues with the other branches all the year.

The twelfth sort grows naturally upon the Alps; this hath a perennial root, from whence arise two or three slender stiff stalks, which divide at the top into two or three slender branches, garnished with spear-shaped leaves placed alternately. The flowers come out singly at the joints, and sit close to the stalks; their empalements are cut into five slender segments, which are longer than the petals of the flower. The flowers are yellow, and appear about the same time with the common sort, and the seeds ripen in the autumn.

The thirteenth sort grows common in many parts of England, upon dry barren hills. It is commonly called *Linum catharticum*, purging Flax, and also Mountain Flax. This rises with several branching slender stalks about seven or eight inches high, garnished with small, oval, spear-shaped leaves placed opposite. The flowers are small and white, standing upon pretty long foot-stalks, which come out from the side of the branches, and also where they are divided. They appear in July, and are succeeded by small round capsules, containing small flat seeds which ripen in the autumn. This is one of those plants which refuses culture. I have frequently sown the seeds both in autumn and spring, but could seldom get up any of the plants, and others who have made the trial have found the same.

The fourteenth sort grows naturally about Montpellier, and in some parts of Italy near the sea. This rises with upright stalks near two feet high, the lower part of which are garnished with spear-shaped leaves placed opposite, but on the upper part they are alternate. The stalks divide upward into several branches, the tops of which are garnished with yellow flowers about the size of those of common Flax, which hang downward; these are succeeded by small oval capsules, containing smaller seeds than those of the common Flax. The flowers appear in July, and the seeds ripen in the autumn.

There are several other species of Flax which grow wild in the different parts of Europe, but those here enumerated are all I have seen growing in the English gardens.

The first sort is that which is cultivated for use in divers parts of Europe, and is reckoned an excellent commodity; the right tilling and ordering of which, is esteemed a good piece of husbandry.

This should be cultivated upon a rich soil, that has not been ploughed for several years, upon which Flax always makes the best improvement; but as it draws greatly from the soil, it should not be sown two years together upon the same ground, nor in less than after five or six years interval.

This ground should be as clean from weeds as possible; in order to have it so, it should be fallowed two winters and one summer, observing to harrow the ground well between each ploughing, particularly in summer, to destroy the young weeds soon after they appear, that the smallest of them may not stand to ripen their seed; this will also break the clods, and separate their parts so, that they will fall to pieces on being stirred. If the land should require dung, that should not be laid on till the last ploughing, when it must be buried in the ground; but this dung should be such as is clear from the seeds of weeds, which it always will be where there is care taken to keep the dunghills clean from weeds, and the places near it; for supposing there should be any seeds at first among the dung, yet when it is laid in a heap and well fermented, that will destroy the seeds; but there are few persons who are careful to keep their dunghills, and the places near them, clean from weeds; and the seeds of these falling on the dung, are carried upon the land; from whence sprung that vulgar error, that dung produces weeds, which it can never do, if there is not the seeds mixed with it. Just before the

season for sowing of the Flax seed, the land must be well ploughed, laid flat and even, upon which the seeds should be sown about the latter end of March, or the beginning of April, when the weather is mild and warm.

The common way is to sow the seed in broad-cast, and to allow from two to three bushels of seeds to one acre of land; but from many repeated trials, I have found it is a much better method to sow the seeds in drills, at about ten inches distance from each other, by which half the quantity of seed which is usually sown, will produce a greater crop; and when the Flax is thus sown, the ground may be easily hoed to destroy the weeds; which, if twice repeated in dry weather, will keep the ground clean till the Flax is ripe: this may be performed at half the expence which the hand weeding will cost, and will not tread down the plants nor harden the ground, which by the other method is always done; and it is absolutely necessary to keep the Flax clean from weeds, otherwise they will overbear and spoil the crop.

There are some people who recommend the feeding of sheep with Flax, when it is a good height; and say, they will eat away the weeds and Grass, and do the Flax good; and if they should lie in it, and beat it down or flatten it, it will rise again the next rain: but this is a very wrong practice, for if the sheep gnaw or eat the Flax, the plants will shoot up very weak, and never come to half the size they would have done, if not cropped: and as to the sheep destroying the weeds, they never are so nice distinguishers, for if they like the crop better than the weeds, they will devour that and leave the weeds untouched.

Toward the latter end of August or the beginning of September, the Flax will begin to ripen, when you must be careful that it does not stand to be over ripe; therefore you must pull it up as soon as the heads begin to change brown and hang downwards, otherwise the seeds will soon scatter and be lost; so that the pluckers must be nimble, and tie it up in handfuls, setting them upright till they be perfectly dry, and then house them. If the Flax be pulled when it first begins to flower, it will be whiter than if it stand till the seed is ripe, but then the seed will be lost; but the thread will be stronger when Flax is left till the seed is ripe, provided it does not stand too long, but the colour of it will not be so good.

The Siberian perennial Flax has been made trial of, and answers very well for making of common strong linen, but the thread spun from this is not so fine or white as that which is produced from the common sort; but as the roots of this sort will continue many years, so there will be a great saving in the culture, as it will require no other care but to keep it constantly clean from weeds; which cannot be well done, unless the seeds are sown in rows, that the ground may be constantly kept hoed to destroy the weeds when young; for if they are suffered to grow large, it will be difficult to get the ground clean, and they will weaken the roots. This sort must have the stalks cut off close to the ground when ripe, and tied up in small bundles, managing them afterward in the same way as the common sort; but this seldom produces more than three crops, which will pay for standing.

The eighth sort I received from Istria, which produced the finest thread of all the sorts which I have tried; and this grows taller than the common Flax, and having a biennial root, may be worthy of trial to see how it will thrive in the open fields; for in gardens it lives through the winter without receiving the least injury from the frost, the roots having survived through the winter in the Chelsea garden several years; and in order to make trial of its goodness, I gave a parcel of the stalks of this, as also of the Spanish and Siberian perennial sorts, to a person who is well skilled in watering, breaking, and dressing of Flax, who prepared them, and assured me, that the Istrian Flax was by much the finest of the three, and was in goodness preferable to any he had seen.

L I P

There is annually great quantities of the seed of Flax imported into Scotland and Ireland, from the East Country, particularly from Riga, to the amount of many thousand pounds sterling, per ann. which might be saved to the public, by encouraging the growth of Flax in the northern colonies of America, where the summers are warmer than in England, so that the seeds would ripen perfectly there, and the change of seeds from thence would be greater than that from Riga, but it should be confined to the most northern parts of America; for such seeds as are saved in the warmer parts will not succeed well here, as I have experienced in many other kinds of plants, whose seeds I have sent to Carolina, where they have grown two or three years, after which some of the seeds have been sent me back, which I have always found to be much longer in growing to perfection than before.

The other sorts which are here mentioned, are preserved in gardens for the sake of variety, but none of them are used, except the Mountain Flax, which is esteemed a good purger in dropical disorders, and has of late years been often prescribed.

They are all of them propagated by seeds, which may be sown in the spring, in the places where they are to remain, and will require no other culture but to keep the plants clean from weeds. The annual sorts will flower and perfect their seeds the same year, but the roots of the perennial sorts will continue several years, putting out fresh stalks every spring. The shrubby sorts will live through the winter in the open air, provided it is in a dry soil and a warm situation; but these rarely produce seeds in England.

The method of watering, piling, braking, &c. being a particular business, and foreign to my design, I shall not pretend to give any directions about it in this place.

The common sort is a plant of the greatest use, in several of the most essential parts of life; from the seeds an expressed oil is drawn, which is of great use in medicine, painting, &c. from the bark of the stalks is made linen, and from the rags of linen is made paper; so that this plant may be esteemed as one of the most valuable, and absolutely necessary in many of the principal conveniences of life.

LINUM UMBILICATUM. See CYNOGLOSSUM.

LIPPIA. Houst. Gen. Nov. Lin. Gen. Plant. 699.

This plant was so named by the late Dr. William Houstoun, who discovered it at La Vera Cruz, where it grows naturally, in honour of Dr. Augustus Lippi, a famous botanist, who travelled to Egypt, and discovered many new plants.

The CHARACTERS are,

The empalement of the flower is permanent, roundish, and compressed. The flower hath one petal, which is of the ringent kind; the upper lip is divided into two parts, which are reflexed; the under lip is smaller, and cut into two roundish segments. It hath four short stamina, two of which are a little longer than the other, terminated by single summits, and an oval germen supporting a slender style the length of the stamina, crowned by an indented stigma. The germen afterward turns to a compressed capsule with one cell, opening with two valves, which appear like the scales of the empalement, inclosing two seeds which are joined.

This genus of plants is ranged in the second section of Linnæus's fourteenth class, intitled Didynamia Angiospermia, which includes those plants whose flowers have two long and two shorter stamina, and the seeds are included in capsules.

The SPECIES are,

1. **LIPPIA** (*Americana*) *arborescens foliis conjugatis oblongis, capitulis squamosis & rotundis.* Houst. *Tree Lippia with oblong leaves growing by pairs, having round scaly heads. Lippia capitulis pyramidalis.* Lin. Sp. 883. *Lippia with pyramidal heads.*

2. **LIPPIA** (*Hemisphærica*) *capitulis hemisphæricis.* Jacq. Amer. 25. *Lippia with hemispherical heads.*

The first sort in the country of its native growth, commonly rises to the height of sixteen or eighteen

L I Q

feet, with a rough bark: the branches come out by pairs opposite, as do also the leaves, which are oblong, pointed, and a little sawed on their edges. From the wings of the leaves come out the foot-stalks, which sustain many pyramidal scaly heads, about the size of a large gray Pea, in which are many small yellow flowers appearing between the scales, which are succeeded by the seed-vessels.

The second sort grows naturally in Carthage in New Spain, where it rises with shrubby stalks ten or twelve feet high, sending out slender branches toward their top, garnished with oval spear-shaped leaves three inches long, ending in acute points, smooth on their upper surface, which are placed opposite; the foot-stalks of the flowers come out opposite just above the leaves, each supporting a pyramidal head of white flowers, which peep out from the scales of the head; these are succeeded by capsules having two cells, including small seeds.

The seeds of the first sort were sent by Dr. Houstoun to several curious gardens in Europe, where some of the plants have been raised; but as the country from whence they came is very warm, so the plants will not thrive in this climate, unless they are preserved in a warm stove. The seeds should be sown on a hot-bed, and the plants may be treated in the same manner as other shrubby plants which are natives of warm countries: which is, to keep them always in the stove, plunged in the bark-bed, observing to give them a large share of air in warm weather, and frequently refresh them with water; but in winter they must be watered more sparingly, and be kept in a moderate degree of warmth, otherwise they will not live through the winter, especially while they are young; but when they have acquired strength, they may be preserved with a less share of warmth.

As the plants advance in their growth, they should be shifted into larger pots, but this should not be too often repeated; for if they are removed into new pots every spring, it will be as often as they will require; so that when these, and many other exotic plants, are too often removed, they do not thrive so well as when they are permitted to fill the pots with their roots. The best time to shift these plants is in April, at which time the tan of the hot-bed should be stirred, and fresh tan mixed with it, to increase the heat. The earth in which these plants are placed, should be fresh and light, but not too rich.

LIQUIDAMBER. Mitch. Gen. 12. Lin. Gen. Plant. 955. Liquidamber, Sweet Gum, or Storax-tree.

The CHARACTERS are,

It hath male and female flowers sometimes on the same plant, at other times upon different plants; the male flowers are numerous, disposed in long, loose, conical catkins; these have four-leaved empalements, but no petals. They have a great number of short stamina joined in one body, which are convex on one side, but plain on the other, terminated by erect twin summits, with four furrows. The female flowers are often situated at the base of the male spike, collected in a globe; these have a double empalement like that of the male, and each of them has a bell-shaped, angular, distinct empalement, with many protuberances. They have no petals, but an oblong germen fastened to the empalement, supporting two awl-shaped styles, to which is also fixed the recurved stigmas, which are hairy and as long as the styles. The empalement afterward turns to a roundish capsule of one cell, with two valves at the top, which are acute, and collected in a ligneous globe, containing oblong acute-pointed seeds.

This genus of plants is ranged in the eighth section of Linnæus's twenty-first class, which includes those plants with male and female flowers, whose male flowers have many stamina.

The SPECIES are,

1. **LIQUIDAMBER** (*Styraciflua*) *foliis quinquelobatis serratis. Liquidamber with sawed leaves having five lobes.* *Styrax aceris folio.* Raii Hist. 1681. *Maple-leaved Storax-tree.*

2. **LIQUIDAMBER** (*Orientalis*) foliis quinquelobatis, sinuatis obtusis. Liquidamber with leaves having five lobes, which are sinuated and obtuse.

The first sort has by some writers been ranged with the Maple, but on no other account, except from the similitude of the leaves; for in flower and fruit it is very different from the Maple, and most other genera: nor has it any affinity to the Storax-tree, but the gum which issues from this tree being transparent, and having a great fragranc, has by some ignorant persons been taken for that.

It grows plentifully in Virginia and several other parts of North America, where it rises with a strait naked stem to the height of fifteen or sixteen feet, and afterward branches out regularly to the height of forty feet or upward, forming a pyramidal head. The leaves are angular, and shaped somewhat like those of the lesser Maple, having five lobes, but are of a dark green colour, and their upper surfaces shining; a strong, sweet, glutinous substance exudes through the pores of the leaves in warm weather, which renders them clammy to the touch.

The flowers are generally produced early in the spring of the year, before the leaves are expanded, which are of a Saffron colour, and grow in spikes from the extremity of the branches; after these are past, the fruit swells to the size of a Walnut, being perfectly round, having many protuberances, each having a small hole and a short tail, which extends half an inch.

The planks of this tree being beautifully veined, are often used in America for wainscoting rooms; but it requires a long time to season the boards, otherwise they are apt to shrink.

In Europe this tree is cultivated in the gardens of the curious, for the sake of variety; it is hardy enough to endure the severest cold of this country in the open air, and there are some of them upward of twenty feet high, though I have not heard of any of them which has produced fruit.

This is commonly propagated by layers in England, but those plants which are raised from seeds grow to be much fairer trees.

The seeds of this tree, if sown in the spring, commonly remain in the ground a whole year before the plants come up; so that the surest way to raise them is, to sow the seeds in boxes or pots of light earth; which may be placed in a shady situation during the first summer, and in autumn they may be removed where they may have more sun; but if the winter should prove severe, it will be proper to cover them with Peas-haulm, or other light covering, which should be taken off constantly in mild weather. In the following spring, if these boxes or pots are placed upon a moderate hot-bed, it will cause the seeds to come up early, so that the plants will have time to get strength before the winter; but during the first and second winters, it will be proper to screen the plants from severe frost, but afterward they will bear the cold very well.

The seeds of the second sort were sent by Mr. Peyssonel from the Levant, to the French king's garden at Marli, a few of which were sent me by Mr. Richard, the king's gardener, which succeeded in the Chelsea garden. The leaves of this sort differ from those of the first, in having their lobes shorter, and much more sinuated on their borders; they end in blunt points, and are not serrated; but as I have not seen the fruit of this, so I do not know how it differs from the other.

LIRIODENDRUM. See **TULIPIFERA.**

LITHOSPERMUM. Tourn. Inst. R. H. 137. tab. 55. Lin. Gen. Plant. 166. [of *Λίθος*, a stone, and *σπέρμα*, seed; q. d. Stone-seed; because the seed of this plant is hard, and good against the stone.] Gromwell, Gromill, or Graymill; in French, *Gremil*.

The CHARACTERS are,

The flower hath an oblong, erect, acute-pointed, permanent, empalement, which is cut into five parts. It hath one petal with a cylindrical tube the length of the em-

palement, divided into five obtuse points at the brim, which are erect; the chaps are perforated. It hath five short stamina terminated by oblong summits, which are shut up in the chaps of the petal. It hath four germen, with a slender style the length of the tube, crowned by a bifid obtuse stigma. The germen afterward turn to so many oval, hard, smooth, acute-pointed seeds, sitting in the spreading empalement.

This genus of plants is ranged in the first section of Linnæus's fifth class, which includes the plants whose flowers have five stamina and one style.

The SPECIES are,

1. **LITHOSPERMUM** (*Officinale*) feminibus lævibus, corollis calycem vix superantibus, foliis lanceolatis. Hort. Cliff. 46. Gromwell with smooth seeds, the petal of the flower scarce longer than the empalement, and spear-shaped leaves. *Lithospermum majus erectum*. C. B. P. 258. Greater upright Gromwell.
2. **LITHOSPERMUM** (*Arvense*) feminibus rugosis, corollis vix calycem superantibus. Hort. Cliff. 46. Gromwell with rough seeds, whose petals are scarce longer than the empalement. *Lithospermum arvense*, radice rubra. C. B. P. 258. Field Gromwell with a red root.
3. **LITHOSPERMUM** (*Purpureo-ceruleum*) feminibus lævibus, corollis calycem multoties superantibus. Hort. Cliff. 46. Gromwell with smooth seeds, and the petal many times longer than the empalement. *Lithospermum minus repens latifolium*. C. B. P. 258. Smaller, creeping, broad-leaved Gromwell.
4. **LITHOSPERMUM** (*Virginianum*) foliis subovalibus nervosis, corollis acuminatis. Lin. Sp. Plant. 132. Gromwell with veined leaves which are almost oval, and acute-pointed petals. *Lithospermum latifolium Virginianum*, flore albido longiore. Mor. Hist. 3. p. 447. Broad-leaved Gromwell of Virginia with a longer whitish flower.
5. **LITHOSPERMUM** (*Fruticosum*) fruticosum, foliis linearibus hispidis, staminibus corollam subæquantibus. Lin. Sp. 190. Shrubby Gromwell with rough linear leaves, and the stamina almost equal to the petal. *Buglossum samium frutescens*, foliis Rorismarini obscure virentibus lucidis & hirsutis. Tourn. Cor. 6.

The first sort grows naturally upon the banks, and in dry fields in many parts of England, so is seldom admitted into gardens. This hath a biennial root, from which arise two or three upright stalks two feet high, which branch out toward the top, garnished with spear-shaped, rough, hairy leaves, placed alternate, sitting close to the stalks. The flowers come out singly at every joint of the small branches; they are white, of one petal, cut into four parts at the top, and stand within the empalement; these are succeeded by four hard, white, shining seeds, which ripen in the empalement. It flowers in May, and the seeds ripen in August.

The seeds of this plant are accounted a powerful diuretic, and a cleanser of the reins and urethers, being boiled in wine and water, and are of great service against gravel or stoppage of urine.

The second sort is an annual plant, which grows among winter Corn in many parts of England. This rises with a slender branching stalk a foot and a half high, garnished with narrow, spear-shaped, rough leaves placed alternately. The flowers are produced singly on the upper parts of the stalks. They are small and white; these are succeeded by four rough seeds, which ripen in the empalement. It flowers in June, and the seeds ripen in August, soon after which the plants decay.

The third sort grows naturally in woods in many parts of England; this hath a perennial root, from which come out two or three trailing stalks scarce a foot long, garnished with long, narrow, spear-shaped leaves, placed alternately; these are smoother than those of the other sorts. The flowers are produced at the end of the stalks from amongst the leaves; they are white, and the petals are much longer than the empalements. These appear the latter end of May, and each is succeeded by four smooth seeds, which ripen in the empalement.

The

LOB

The fourth sort grows naturally in North America; this hath a perennial root, from which arise several very hairy stalks about a foot and a half high, garnished with rough, hairy, veined leaves, which are almost oval, sitting close to the stalks alternately. The flowers grow in short reflexed spikes at the end of the branches: these are white, their petals being longer than the empalement, ending in acute points. It flowers in June, and the seeds ripen in autumn.

The fifth sort grows naturally in the south of France, and also in the Levant. This hath a perennial root, which runs deep in the ground, from which comes out in the spring a shrubby erect stalk two or three feet high, which is pretty closely set with hairs, and garnished with narrow leaves placed alternately. The flowers are produced in short reflexed spikes at the end of the stalk, standing in hairy empalements; they are of a reddish purple colour, but as they decay change to a deep purple; they are tubulous, but cut at the top into four or five segments; the upper two are reflexed. It flowers in June, but the seeds rarely ripen in England.

These plants may be cultivated by sowing their seeds in rows soon after they are ripe, in a bed of fresh earth, allowing the rows at least a foot distance from each other, observing to keep them clear from weeds, and they will thrive in almost any soil or situation.

LOAM is a common superficial earth, that is a mixture of sand and clay, commonly of a yellowish colour, though there is some Loam that is blackish. Some call Loam the most common superficial earth met with in England, without any regard to the proportion it bears to sand or clay; but most generally the appellation of Loam is applied to a soft fat earth, partaking of clay, but easy to work.

It is found by experience, that plants of most sorts will grow in it; and wherever it is found, it appears to be a more beneficial soil to plants than any other.

A clay used in grafting is also called Loam.

LOBELIA. Plum. Nov. Gen. 21. tab. 31. Lin. Gen. Plant. 897.

The CHARACTERS are,

The empalement of the flower is small, of one leaf, indented in five parts, and grows about the germen. The flower has but one petal, which is tubulous, and a little ringent, cut into five parts at the brim; two of the upper segments are smaller than the other, are more reflexed and deeper cut, these constitute the upper lip; the three lower are spread open, and larger. It hath five awl-shaped stamina the length of the tube, terminated by oblong cylindrical summits, divided at their base into five parts. It has a pointed germen under the petal, supporting a cylindrical style, crowned by an obtuse prickly stigma. The germen afterward becomes an oval fleshy berry with two cells, each containing a single seed.

This genus of plants is ranged in the fifth section of Linnaeus's nineteenth class, to which he has joined the Rapuntium of Tournefort; but although the form of the flowers, and the number of their stamina, agree pretty well, yet as the fruit of this is a pulpy berry, inclosing but two seeds, and the Rapuntii have dry capsules including many small seeds, I shall keep them separate.

We know but one SPECIES of this genus, viz.

LOBELIA (*Frutescens*) frutescens, foliis ovati-oblongis integerrimis. Flor. Zeyl. 313. *Shrubby Lobelia with oblong, oval, entire leaves.* Lobelia frutescens portulacæ folio. Plum. Nov. Gen. 21. *Shrubby Lobelia with a Purslane leaf.*

This plant rises with a succulent stalk five or six feet high, garnished with oval, oblong, succulent leaves, which are placed alternately; these sit close to the stalk. The flowers are produced upon long foot-stalks, which come out from the side of the stalk, and sustain two or three white flowers of one petal, cut into five acute segments at the brim; these are succeeded by two oval berries as large as Bullace, containing a stone with two cells, in each of which is lodged a single seed.

LON

The seeds of this plant were sent to England by Mr. Catesby, in the year 1724, who gathered them in the Bahama Islands, where the plants grow in plenty, near the shore of the sea; and since that time the seeds have been sent to England by Dr. William Houstoun, who gathered them at La Vera Cruz; so that I believe the plant is common in most of the warm parts of America.

It is propagated by seeds, which must be procured from the countries of its natural growth, for the plants will not produce them in Europe; these seeds should be sown in pots filled with light sandy earth, and plunged into a hot-bed of tanners bark, where the plants will come up in about a month or five weeks, provided the bed is warm, and the earth often watered. When the plants are up, they should be kept in a temperate hot-bed, and frequently refreshed with water, but it must not be given them in large quantities, for they are very succulent, and subject to perish with much moisture, especially while they are young. When the plants are about two inches high, they should be carefully taken out of the pots in which they were sown, and each planted in a separate small pot filled with fresh light sandy earth, and then plunged into the hot-bed again, observing to shade them in the heat of the day until they have taken new root. In this hot-bed the plants may remain until the middle, or latter end of September, when they must be removed into the stove, and plunged into the tan-bed, in the warmest part of the stove, for they are very tender plants while young, therefore must be kept very warm, otherwise they will not live through the first winter in this country. In the spring following the plants may be shifted into somewhat larger pots, and then plunged into a fresh hot-bed to forward their growth; for if they are not pushed on while they are young, they seldom grow to any size, nor will they ever flower; so that in order to have them in any beauty, they must be carefully managed. The leaves of this plant are very subject to contract filth, by being constantly kept in the stove, therefore they should be washed with a sponge frequently, to keep them clean, otherwise they will appear unsightly.

LOBUS ECHINATUS. See GUILANDINA.

LOCULAMENTS are little distinct cells, or partitions, within the seed-vessels of plants.

LOLIUM. Darnel Grass.

Of this sort of Grass we have two or three species, which grow naturally in England; some in dry Grass grounds, and one which is an annual Grass, is frequently found in arable land; but as neither of them are cultivated for use, so I shall not trouble the reader with any farther account of them.

LONCHITIS [so called of Ἀλγῆν, a lance or spear, because the leaves are so sharp-pointed as to resemble the point of a spear.] Rough Spleenwort.

The CHARACTERS are,

The leaves are like those of the Fern, but the pinnule are eared at their base; the fruit also is like that of the Fern.

The SPECIES are,

1. LONCHITIS aspera. Ger. *Rough Spleenwort.*
2. LONCHITIS aspera major. Ger. *Emach. Greater rough Spleenwort.*

The first of these plants is very common in shady woods, by the sides of small rivulets, in divers parts of England; but the second sort is not quite so common, and has been brought into several curious botanic gardens from the mountains in Wales. There are also great variety of these plants in America, which at present are strangers in the European gardens; they are seldom cultivated but in botanic gardens for the sake of variety, where they must have a moist soil and shady situation.

LONGITUDINAL VESSELS, in plants, are such as are extended in length through the woody parts of trees and plants, into which the air is supposed to enter, and mix with the juices of the plant, and thereby augment its bulk.

LONI-

LONICERA. Lin. Gen. Plant. Chamæcerasus. Tourn. Inst. R. H. 609. tab. 379. Upright Honeyfuckle.

The CHARACTERS are,

The flower has a small empalement, cut into five parts, upon which the germen sits. It hath one petal, with an oblong tube, cut into five parts at the brim, and five awl-shaped stamina, almost the length of the petal, terminated by oblong summits. Under the petal is situated a roundish germen, supporting a slender style the length of the petal, crowned by an obtuse stigma. The germen afterward turns to two berries, which join at their base.

This genus of plants is ranged in the first section of Linnæus's fifth class, which includes those plants whose flowers have five stamina and one style; and to this genus he has joined the Caprifolium, Periclymenum, and Xylosteum of Tournefort, and the Symphoricarpos of Dillenius. Tournefort places this genus in the sixth section of his twentieth class, in which he ranges the trees and shrubs with a flower of one petal, whose empalement becomes a berry.

The SPECIES are,

1. LONICERA (*Xylosteum*) pedunculis bifloris, baccis distinctis, foliis integerrimis pubescentibus. Prod. Leyd. 238. *Lonicera with two flowers on each foot-stalk, distinct berries, and entire woolly leaves.* Chamæcerasus dumetorum fructu gemino rubro. C. B. P. 451. *Dwarf Cherry with twin red fruit, commonly called Fly Honeyfuckle.*
2. LONICERA (*Alpigena*) pedunculis bifloris, baccis coadunatis didymis. Lin. Sp. Plant. 174. *Lonicera with two flowers upon a foot-stalk, and twin berries which are joined together.* Chamæcerasus Alpina, fructu gemino rubro duobus punctis notato. C. B. P. 451. *Dwarf Alpine Cherry with a red twin fruit, marked with two points, commonly called red-berried upright Honeyfuckle.*
3. LONICERA (*Cerulea*) pedunculis bifloris, baccis coadunatis globosis, stylis indivisis. Lin. Sp. Plant. 174. *Lonicera with two flowers on a foot-stalk, globular berries, which are joined, and undivided styles.* Chamæcerasus montana, fructu singulari-ceruleo. C. B. P. 451. *Mountain Dwarf Cherry with a single blue fruit, commonly called single, blue-berried, upright Honeyfuckle.*
4. LONICERA (*Nigra*) pedunculis bifloris, baccis distinctis, foliis ferratis. Prod. Leyd. 238. *Lonicera with two flowers on a foot-stalk, distinct berries, and sawed leaves.* Chamæcerasus Alpina, fructu nigro gemino. C. B. P. 451. *Alpine Dwarf Cherry with a black twin fruit, called black-berried upright Honeyfuckle.*
5. LONICERA (*Tartarica*) pedunculis bifloris, baccis distinctis, foliis cordatis obtusis. Hort. Upsal. 42. *Lonicera with two flowers on a foot-stalk, distinct berries, and blunt heart-shaped leaves.* Chamæcerasus fructu gemino rubro, foliis glabris cordatis. Amm. 7. LONICERA (*Symphoricarpos*) capitulis lateralibus pedunculatis, foliis petiolatis. Lin. Sp. Plant. 175. *Lonicera with lateral heads of flowers growing upon foot-stalks, and leaves having foot-stalks.* Symphoricarpos foliis alatis. Dill. Hort. Elth. 371. *commonly called shrubby St. Peterfwort.*

The first sort has been many years cultivated in the English gardens under the title of Fly Honeyfuckle. It grows naturally upon the Alps, and in other cold parts of Europe. It rises with a strong woody stalk six or eight feet high, covered with a whitish bark, dividing into many branches, which are garnished with oblong oval leaves placed opposite; they are entire, and covered with short hairy down. The flowers come out on each side of the branches opposite, standing upon slender foot-stalks, each sustaining two white flowers standing erect; these have one petal, which is cut into five parts; the three lower being narrow, are reflexed, the two broader stand upright; these appear in June, and are succeeded by

two red clammy berries, which are joined at their base; and ripen the beginning of September.

The second sort grows naturally upon the Alps; this has been long cultivated in the English gardens, by the title of red-berried upright Honeyfuckle; this hath a short, thick, woody stem, which divides into many strong woody branches growing erect, garnished with spear-shaped leaves placed opposite, standing upon foot-stalks; they are entire, their under side being of a pale green, but their upper of a dark green. The flowers stand upon very long slender foot-stalks, which come out opposite on each side the branches, at the base of the leaves; they are red on their outside, but pale within, shaped like those of the former sort, but are a little larger, standing erect; these appear the latter end of April, and are commonly succeeded by two oval red berries, joined at their base, which have two punctures; they ripen the beginning of August. Sometimes there is but one berry succeeding each flower, which is frequently as large as a Kentish Cherry; this I believe has led some to suppose it was a distinct species, as I thought myself, when I saw all the fruit upon the shrub were single; but the following years, I found they had twin fruit like the others.

The third sort grows naturally upon the Appenines; this is a shrub of humbler growth than either of the former, seldom rising more than four or five feet high. The branches are slender, covered with a smooth purplish bark. The joints are distant, where the leaves come out opposite, and sometimes there are two on each side. The foot-stalks of the flowers are very short, each sustaining two white flowers, shaped like those of the former sorts; these are succeeded by blue berries, which are single and distinct. The flowers appear in May, and the berries ripen in August.

The fourth sort grows naturally on the Alps and Helvetian Mountains; this is a shrub very like the former, but the branches are slenderer. The leaves are a little sawed on their edges. The flowers have two berries succeeding them, in which consists their difference. It flowers at the same time with the former.

The fifth sort grows naturally in Tartary, from whence the seeds were sent to the Imperial Garden at Petersburg, where they succeeded, and from thence the seeds were sent to me; this is a shrub which grows about the same height with the two former, to which this has a great resemblance in its branches; but the leaves of this are heart-shaped, and the berries are red, growing sometimes single, at others double, and frequently there are three joined together, which are about the same size with the former. It flowers in April, and the fruit is ripe in July.

The sixth sort grows naturally on the Pyrenean Mountains, and also in Canada, from whence the seeds were brought to Duke D'Ayen, which were sown in his curious garden at St. Germain, where they succeeded, and his highness was so good as to furnish me with a plant; this seldom rises more than three or four feet high, dividing into several spreading irregular branches, which are garnished with oblong smooth leaves, placed opposite. The flowers come out from the side of the branches upon slender foot-stalks, each sustaining two white flowers, which are cut into five segments almost to the bottom; these are succeeded by berries as the other sorts. It flowers in April.

The seventh sort grows naturally in North America, but has been many years propagated in the English gardens; this hath a shrubby stalk which rises about four feet high, sending out many slender plain branches, garnished with oval hairy leaves, placed by pairs opposite, having very short foot-stalks. The flowers are produced in whorls round the stalk; they are of an herbaceous colour, and appear in August. The fruit, which is hollow, and shaped like a pottage pot, ripens in the winter. Dr. Dillenius, in his Hortus Elthamensis, has titled this plant, Symphoricarpos foliis alatis, supposing the leaves to be winged; but

L O P

but as the leaves fall off single, and the branches remain upon which they were fixed, they cannot be called winged leaves.

These shrubs are now propagated in the nursery-gardens near London, for sale, and are commonly intermixed with other flowering shrubs for the sake of variety; but as there is little beauty in some of their flowers, a few of them only should be admitted, to set off those which are preferable; they are all of them very hardy plants, so will thrive in a cold situation better than in a warm one; they love a moist soil, in which they will thrive, and produce a greater quantity of fruit than in dry ground.

They may be propagated either by seeds or cuttings. The seeds commonly lie in the ground a year before they vegetate, but require no particular culture; if they are sown in autumn, many of them will grow the following spring. The cuttings should be planted in autumn in a shady border, where they will put out roots the following spring, and in the following autumn they may be removed into a nursery, to grow two years to get strength, after which they should be transplanted where they are designed to remain.

LOPPING. It is very observable, that most old trees are hollow within, which does not proceed from the nature of the trees, but is the fault of those who have the management of them, who suffer the tops to grow large before they lop them, as the Ash, Elm, Hornbeam, &c. and persuade themselves, that they may have the more great wood; but, in the mean time, do not consider that the cutting off great tops, or branches, endangers the life of a tree, or, at best, wounds it so, that many trees yearly decay more in their bodies, than the yearly tops come to; and at the same time that they furnish themselves with more great wood, they do it at the loss of the owner. And, indeed, though the Hornbeam and Elm will bear great tops when the body is little more than a shell, yet the Ash, if it comes to take wet at the head, very rarely bears more top after the body of the tree decays; therefore, if once these trees decay much in the middle, they will be worth little but for the fire, so that if you find a timber tree decay, it should be cut down in time, that the timber be not lost.

The Lopping of young trees, that is, at ten or twelve years old at most, will preserve them much longer, and will occasion the shoots to grow more into wood in one year, than they do in old tops at two or three. But when great boughs are ill taken off, it often spoils many a tree, for which reason they should always be spared, unless there is an absolute necessity. When they must be cut off, it should be close and smooth, and not parallel to the horizon, and cover the wound with loam and horse-dung mixed, to prevent the wet from entering the body of the tree.

When trees are at their full growth, there are several signs of their decay, as, the withering or dying of many of their top branches; or if the wet enters at any knot, or they are any-wise hollow, or discoloured, if they make but poor shoots, or if woodpeckers make any holes in them.

This Lopping of trees is only to be understood for pollard trees, because nothing is more injurious to the growth of timber trees, than that of Lopping or cutting off great branches from them; whoever will be at the trouble of trying the experiment upon two trees of equal age and size, growing near each other, to lop or cut off the side branches from one of them, and suffer all the branches to grow upon the other, will, in a few years, find the latter to exceed the other in growth every way, and this will not decay near so soon.

All sorts of resinous trees, or such as abound with a milky juice, should be lopped very sparingly, for they are subject to decay when often cut. The best season for Lopping these trees, is soon after Bartholomew tide, at which time they seldom bleed much, and the

L O T

wound is commonly healed over before the cold weather comes on.

LORANTHUS. Vaill. Act. R. Sc. 1702. Lin. Gen. Plant. 400. Lonicera. Plum. Nov. Gen. 17. tab. 37.

The CHARACTERS are,

The empalement of the flower is entire, concave, and crowns the germen. The flower is tubulous, and cut into five narrow segments almost to the bottom, which are reflexed. It hath four stamina which are longer than the tube of the flower, terminated by globular summits. The germen, which is situated below the empalement, supports a single style which is longer than the stamina, crowned by an oval stigma. The germen afterward becomes an oval pulpy fruit with one cell, including several compressed seeds.

This genus of plants is ranged in the first section of Linnæus's sixth class, but it should be placed in his fourth class, for the flower has but four stamina and one style.

There are several species of this genus, which grow naturally upon trees, in several parts of America; but as the plants cannot be cultivated in gardens, so it will be to no purpose to enumerate them.

LOTUS. Tourn. Inst. R. H. 402. Lin. Gen. Plant. 803. Bird's-foot Trefoil; in French, *Lotier*.

The CHARACTERS are,

The empalement of the flower is of one leaf, permanent, and cut at the top into five parts. The flower is of the butterfly kind. The standard is roundish, and reflexed backward. The wings are broad, roundish, and shorter than the standard, closing together at the top. The keel is closed on the upper side, and convex on the under, rising a little. It hath ten stamina, nine joined and one separate, terminated by small summits, with an oblong taper germen, supporting a single style, crowned by an inflexed stigma. The germen afterward becomes a close cylindrical pod with one cell, opening with two valves, having many transverse partitions, in each of these is lodged one roundish seed.

This genus of plants is ranged in the third section of Linnæus's seventeenth class, intitled *Diadelphia Decandria*, which contains the plants whose flowers have ten stamina in two houses.

The SPECIES are,

1. **Lotus (Corniculatus)** capitulis depressis, caulibus decumbentibus, leguminibus cylindricis patentibus. Lin. Sp. Plant. 775. *Bird's-foot Trefoil with depressed heads, trailing stalks, and cylindrical spreading pods.* Lotus corniculata glabra, minor. J. B. 2. 356. *Lesser, smooth, corniculated Bird's-foot Trefoil.*
2. **Lotus (Angustissimus)** leguminibus subbinatis linearibus strictis erectis, caule erecto, pedunculis alternis. Lin. Sp. Plant. 774. *Bird's-foot Trefoil with erect, linear, strait pods, growing in pairs, an erect stalk, and alternate foot-stalks.* Lotus pentaphyllos, minor, hirsutus, siliqua angustissima. C. B. P. 332. *Smaller, five-leaved, hairy Bird's-foot Trefoil, with very narrow pods.*
3. **Lotus (Glabrus)** capitulis depressis, caulibus decumbentibus, foliis linearibus glabris, leguminibus linearibus. *Bird's-foot Trefoil with depressed heads, trailing stalks, smooth linear leaves, and very narrow pods.* Lotus pentaphyllos frutescens, tenuissimis glabris foliis. C. B. P. 332. *Shrubby five-leaved Bird's-foot Trefoil, with very narrow smooth leaves.*
4. **Lotus (Rectus)** capitulis subglobosis, caule erecto, leguminibus rectis glabris. Hort. Upsal. 221. *Bird's-foot Trefoil with globular heads, an erect stalk, and strait smooth pods.* Lotus villosus, altissimus, flore glomerato. Tourn. Inst. R. H. 403. *Tallest hairy Bird's-foot Trefoil with a glomerated flower.*
5. **Lotus (Cretica)** leguminibus subternatis, caule fruticoso, foliis sericeis nitidis. Hort. Cliff. 372. *Bird's-foot Trefoil with generally three pods on each foot-stalk, a shrubby stalk, and shining leaves.* Lotus argentea Cretica. Pluk. Alm. 226. *Silvery Bird's-foot Trefoil of Crete.*

LOT

6. *Lotus (Hirsutus)* capitulis hirsutis, caule erecto hirsuto, leguminibus ovatis. Hort. Upsal. 220. *Bird's-foot Trefoil with hairy heads, an erect hairy stalk, and oval pods.* *Lotus pentaphyllos filiquosus villosus.* C. B. P. 332. *Five-leaved, hairy, podded Bird's-foot Trefoil.*
7. *Lotus (Candidus)* capitulis subglobosis hirsutis, caule erecto ramoso, hirsuto, foliis tomentosis. *Bird's-foot Trefoil with globular heads, which are hairy, an upright branching hairy stalk, and woolly leaves.* *Lotus hæmorrhoidalis humilior & candidior.* Tourn. Inst. 403. *Lower bird's-foot Trefoil, having whiter leaves.*
8. *Lotus (Ornithopodioides)* leguminibus subquinatis arcuatis compressis, caulibus diffusis. Hort. Cliff. 372. *Bird's-foot Trefoil with five arched compressed pods, and diffused stalks.* *Lotus filiquis ornithopodii.* C. B. P. 332. *Bird's-foot Trefoil with pods like birds feet.*

Cliff. 372. *Bird's-foot Trefoil with three pods, an erect herbaceous stalk and narrow leaves.* *Lotus angustifolia, flore luteo purpurascente, insulæ St. Jacobi.* Hort. Amst. 2. p. 165. *Narrow-leaved Bird's-foot Trefoil of St. James's island, with a yellow purplish flower.*
17. *Lotus (Dorycnium)* capitulis aphyllis, foliis sessilibus quinatis. Lin. Sp. Plant. 776. *Bird's-foot Trefoil with naked heads, and leaves placed by fives sitting close to the branches.* *Dorycnium Monspeliensium.* Lob. Icon. 51. *Dorycnium of Montpellier.*
The first, second, and third sorts grow naturally in many parts of England, so are rarely admitted into gardens. When these grow in moist land and a shady situation, they send out stalks near two feet long; but upon dry chalky and gravelly ground, their stalks are not more than four or five inches long, and lie flat upon the ground. I have always observed

LOT

in those pastures where these plants have grown, that the cattle of all sorts have avoided eating them, but the Grass all round them has been eaten very bare. I have cut the plants when young, and given it to various kinds of animals, but could never get them to eat it; and yet the seeds of these have been gathered and sold by some quacks in husbandry, under the title of Lady's Finger Grass, to be sown as an improvement to land for pasture.

The roots of these are perennial, so are difficult to get out when they have had long possession of the land; and they produce great quantities of seeds, which is cast about by the elasticity of the pods when ripe, to a considerable distance; they flower in June, and the seeds ripen in September.

The fourth sort grows naturally in the south of France, in Italy, and Sicily; this has by some been supposed the Cytisus of Virgil, but without foundation, for it does not answer the description given of that plant. This hath a strong perennial root, from which arise many upright strong stalks from three to four feet high, covered with a purplish bark, and toward the top send out a few side branches; these are garnished at every joint by a trifoliate leaf, whose lobes are wedge-shaped; at the base of the foot-stalk are placed two heart-shaped lobes sitting close to the branch; the leaves are hairy on their under side; the flowers are produced at the end of the branches almost in globular heads, sitting close to the foot-stalk: these are of a pale flesh colour and appear in June, and are succeeded by smooth strait pods almost an inch long, which change to a brown colour when ripe, and contain several roundish seeds which ripen in September. It is rarely cultivated but in botanic gardens for variety, but if any person has an inclination to cultivate this plant for feeding of cattle, it may be done in the same way as the Lucern, for which there is full directions in the article MEDICAGO. It rises easily from seeds, is very hardy, and will thrive on any light dry poor ground. Cows and horses will eat this plant when green, but I have not tried if they will feed on it when made into hay.

The fifth sort grows naturally in Syria and Crete; this rises with slender stalks which require support, from three to four feet high, sending out a few side branches; these are garnished at each joint with neat shining silvery leaves which are trifoliate, and have two appendages at the base of their foot-stalks, as the other sorts; they are in shape like the former, but a little smaller, and have an acute point at their top. The foot-stalks of the flowers, which are from two to three inches long, arise from the side of the branches, and sustain heads of yellow flowers, which part in the middle, each head containing four or six flowers; these appear in May, June, and July, and are succeeded by long taper pods filled with roundish seeds which ripen in the autumn.

This sort has a perennial stalk, but is too tender to live through the winter in the open air in England, so is kept in pots and removed into the green-house in autumn, and treated like other hardy exotic plants which only require protection from frost, so want no artificial heat. It may be propagated by seeds, which if sown on a bed of light earth in April, the plants will come up in about a month after, and in another month will be fit to remove; when they should be each put into a separate small pot filled with fresh light earth, placing them in the shade till they have taken new root; then they may be removed to a sheltered situation, where they may remain till autumn.

It may be also propagated by cuttings, which may be planted during any of the summer months, upon a bed of light earth, covering them close with a bell or hand-glass, and screening them from the sun; in about five or six weeks they will have taken root, when they must be inured to bear the open air, and soon after may be planted in pots, and treated in the same way as the seedling plants.

The

LOT

The sixth fort grows naturally in the south of France and Italy; this hath a perennial stalk, which rises three feet high; when the roots are large, they frequently send up several of these stalks, especially if the old ones are cut down; the stalks are hairy, and divide into several branches, which are closely garnished with hoary trifoliate leaves, having two appendages at the base of the stalk; the flowers are collected into heads sitting upon pretty long foot-stalks, which come out of the side of the stalks. They have very hairy empalements, and are of a dirty white colour with a few marks of pale red. They appear in June and July, and are succeeded by short thick pods of a Chestnut colour, containing several roundish seeds which ripen in the autumn. This is propagated by seeds in the same way as the last fort; the plants will live through the winter in the open air in moderate winters, but it will be proper to keep one or two plants in pots to be sheltered in winter, lest those abroad should be destroyed by severe frost.

The seventh fort grows naturally in Sicily; this rises with an upright woody stalk near three feet high, garnished with leaves like the sixth, but they are much whiter, covered with a short woolly down, as are also the stalks; the flowers grow in close heads like the last, and are succeeded by short pods, which contain many yellow seeds. It flowers in summer, and the seeds ripen in autumn. This is too tender to live in the open air in England through the winter, so the plants must be kept in pots and housed during that season. It is propagated in the same way as the fifth fort, and requires the same culture.

The eighth fort grows naturally in Sicily; this is an annual plant, which sends out from the root many stiff stalks from one to two feet high, which divide into many branches growing diffused without any order, and are garnished with trifoliate leaves, having two appendages at their base; the foot-stalks of the flower rise from the wings of the stalks; they are two or three inches long, terminated by a cluster of yellow flowers, which are succeeded by flat pods two inches long, which are bent like an arch, and have many joints, separating the cells in which the seeds are lodged. It flowers in July, and the seeds ripen in autumn, and the plants decay soon after.

This is propagated by seeds, which should be sown early in April upon an open bed or border exposed to the sun, where the plants are to remain: when they come up they must be thinned, leaving them near two feet asunder, and afterwards they must be kept clean from weeds, which is all the culture they require.

The ninth fort grows naturally in Spain and Portugal: this is an annual plant like the former, but doth not branch so much; the small leaves are rounder at their ends, and they are smoother; the foot-stalks are shorter, and seldom sustain more than two flowers; these are succeeded by two very narrow pods about two inches long, which hang downward. This requires the same culture as the former.

The tenth fort grows naturally in the south of France; this hath a perennial root, from which is sent out several hairy stalks near a foot long, garnished with trifoliate hairy leaves, standing upon short foot-stalks, with two appendages at the base of the foot-stalk; the flowers stand upon pretty long foot-stalks singly, which rise from the end of the branches; they have long hairy empalements, with two oblong acute-pointed leaves immediately under them. The flowers are yellow, standing erect, and are succeeded by taper erect pods an inch and a half long. It flowers in June and July, and the seeds ripen in the autumn. It is propagated by seeds, which should be sown where the plants are to remain, and must be treated as the two former forts, but the roots of this will continue several years.

The eleventh fort grows naturally in Sicily and Crete, where the pods are eaten by the poorer inhabitants when they are young. It also grows about Nice, from

LOT

whence I received the seeds. This is an annual plant, from whose roots come out several trailing stalks a foot long, garnished at each joint with trifoliate roundish leaves, having appendages. The flowers stand singly upon long foot-stalks, which arise from the side of the branches; they are yellow and small, and are succeeded by single pods, which are thick, and arched with a deep furrow on the outside. The flowers appear in June and July, and in warm seasons the seeds ripen in the autumn, but in cold summers they will not ripen here. This must have the same culture as the annual forts before mentioned. The twelfth fort grows near the borders of the sea in France, Spain, and Italy; this hath a perennial root, sending out many slender stalks about a foot and a half long, which trail upon the ground, and are garnished with trifoliate leaves at each joint, which are smooth, and have two appendages to the base of the foot-stalk. The flowers stand singly, upon very long foot-stalks arising from the wings of the stalk; they are yellow, and are succeeded by single pods near two inches long, having four leafy membranes running longitudinally at the four corners. This flowers in June and July, and the seeds ripen in the autumn. It is propagated by seed in the same way as the tenth fort.

The thirteenth fort grows naturally in the south of France and Italy; this is an annual plant, from whose roots are sent forth several branching stalks a foot long, garnished with trifoliate leaves, whose lobes are acute-pointed, and have two oblong oval appendages at the base of their foot-stalks: the foot-stalks of the flower arise from the wings of the branches, each sustaining two yellow flowers, which are succeeded by taper pods near two inches long, having four leafy membranes running longitudinally their length. It flowers in July, and the seeds ripen in autumn. It is propagated by the seeds in the same way as the annual forts before mentioned.

The fourteenth fort grows naturally in Sicily, but has been long cultivated in the English gardens; it was formerly cultivated as an esculent plant. The green pods of it were dressed and eaten as Peas, which the inhabitants of some of the northern counties still continue, but they are very coarse, so not agreeable to the taste of those who have been accustomed to better fare.

It is an annual plant which is cultivated in the flower-gardens near London for ornament. This sends out from the root several decumbent stalks about a foot long, garnished at each joint with trifoliate oval leaves, having oval appendages at the base of their foot-stalks; from each joint arise alternately the foot-stalks of the flowers, which are from two to three inches long, each sustaining one large red flower at the top, with three leaves just under the flower. After the flower fades, the germen becomes a swelling taper pod two inches long, having four leafy membranes or wings running longitudinally. It flowers in June and July, and the seeds ripen in autumn.

The seeds of this fort are commonly sown in patches, five or six seeds being sown near each other, in the borders of the pleasure-garden, where they are designed to remain. If the seeds all grow, some of the plants may be pulled up, leaving only two or three in each patch, and afterward they will require no other care but to keep them clean from weeds.

The fifteenth fort grows near the borders of the sea, in the south of France and Spain. This is a perennial plant, sending out from the root many stalks, which branch out their whole length, and are garnished with roundish trifoliate leaves with two appendages; they are covered with a woolly down: the flowers stand upon short foot-stalks, four or six growing in a divided head; they are yellow, and appear in July, and are succeeded by taper pods filled with roundish seeds, which ripen in autumn. This is propagated by seeds, which should be sown in the spring in the place where the plants are to remain, and must be treated

L U D

treated in the same manner as the hardy perennial forts before mentioned.

The sixteenth sort grows naturally in the Island of St. James, from whence the seeds were first brought to Europe, but I have since received the seeds from the Cape of Good Hope. This hath a slender stalk which is woody, rising from two to three feet high, sending out many slender herbaceous branches, garnished with narrow white leaves, which are sometimes trifoliate, and at others there are five narrow lobes to each; these sit close to the branches, and are hoary. The flowers are produced from the side of the stalks towards their upper part, upon very slender foot-stalks, each sustaining four or five flowers collected in a head, of a yellowish deep purple colour, which are succeeded by taper slender pods little more than an inch long, containing five or six small roundish seeds. This plant flowers all the summer and autumn, and many times great part of the winter, especially if the plants are placed in a dry airy glass-case, where they may be free from damp, for nothing is more prejudicial to them. It is too tender to live abroad in England, so the plants must be kept in pots; and in the winter placed in a warm airy glass-case, but in the summer they should be placed abroad in a sheltered situation. It may be easily propagated by cuttings, during the summer season, in the same way as the fifth sort, and also by seeds; but the plants which have been two or three times propagated by cuttings, seldom are fruitful.

The seventeenth sort grows naturally about Montpellier; it rises with weak shrubby stalks three or four feet high, sending out many slender branches, which are thinly garnished with small hoary leaves, growing with five lobes in form of a hand; they sit close to the branches. The flowers are produced at the extremity of the branches in small heads; they are very small and white, so make no great appearance; they appear in June, and are succeeded by short pods containing two or three small round seeds which ripen in the autumn. This shrub will live in the open air, if it be planted in a dry soil and a warm situation. It is propagated by seeds, which will come up in any common border.

LOTUS ARBOR See CELTIS.

LOVE-APPLE. See LYCOPERSICON.

LUDVIGIA. Lin. Gen. Plant. 142.

This title was given to this genus of plants by Dr. Linnæus, in honour of M. Christ. Ludwig, of Leipzig, who published Remarks on Rivinus's Method of classing Plants, at Leipzig, in 1737.

The CHARACTERS are,

The empalement of the flower is of one leaf, cut into four segments at the top, and sits upon the germen. The flower consists of four spear-shaped petals, which are equal, and spread open. In the center of the flower is situated the four-cornered pointal, attended by four stamina: the germen afterward becomes a four-cornered fruit, crowned with the empalement, and has four cells which are full of small seeds.

This genus of plants is ranged in the first section of Linnæus's fourth class, which includes those plants whose flowers have four stamina and one style.

We have but one SPECIES of this genus in the English gardens at present, which is

LUDVIGIA (*Alternifolia*) foliis alternis lanceolatis. Lin. Sp. Plant. 118. *Ludvigia with alternate spear-shaped leaves.* Ludvigia capsulis subrotundis. Hort. Cliff. 491. *Ludvigia with roundish capsules.*

We have no English name for this plant, but it is very near akin to the Onagra, or Tree Primrose, from which it differs in the number of stamina.

This plant grows naturally in South Carolina, from whence the late Dr. Dale sent me the seeds. It is annual, and rises with an upright branching stalk a foot high, garnished with spear-shaped leaves placed alternate. The flowers come out singly at the foot-stalks of the leaves; they are composed of four small yellow petals, which spread open, standing upon short foot-stalks, and have four stamina; the flowers are succeeded

L U N

by roundish seed-vessels with four leafy membranes they open in four cells, including many small seeds. It flowers in July, and the seeds ripen in the autumn.

The plants must be raised in a hot-bed in the spring, and treated in the same manner as hath been directed for the Amaranthus; for if they are not brought forward in the spring, they seldom produce good seeds in England.

LUFFA. Tourn. Aët. R. S. 1709. Momordica. Lin. Gen. 967. Egyptian Cucumber.

The CHARACTERS are,

It hath a bell-shaped flower consisting of one leaf, which is divided into five parts to the center; there are male and female flowers on the same plant. The male flowers are produced on short foot-stalks, having no embryos; but the female flowers rest on the top of the embryos, which afterward become a fruit like a Cucumler to outward appearance, but is not fleshy; the inner part consisting of many fibres, which are elegantly netted; and there are three cells which are filled with seeds, which are almost of an oval shape.

We have but one SPECIES of this plant, viz.

LUFFA (*Egyptiaca*) Arabum. Tourn. Aët. R. 170. *The Luffa of the Arabians.*

There are two varieties of this plant, one having white, and the other black seeds; but these are not distinct species.

This plant may be propagated after the same manner as Cucumbers and Melons, by sowing the seeds on a hot-bed the beginning of March; and when the plants are come up, they must be pricked into a fresh hot-bed to strengthen the plants, observing to let them have fresh air every day in warm weather, and to refresh them frequently with water. When the plants have four or five leaves, they should be planted out upon a hot-bed where they are designed to remain, which should be under frames, and but one plant put into each light; for as these plants send forth a great number of side-shoots, so where they are planted too close, they will entangle one into the other, and become so thick, as to cause the fruit to drop. In the management of these plants, after they are planted out for good, there must be the same care taken as for Melons and Cucumbers, with this difference only, that these require a larger share of air in warm weather; otherwise the Vines will grow weak, and will not produce fruit.

When the plants have spread, so as to fill the frames on every side, the frames should be raised on bricks, and the ends of the plants drawn out, that they may have room to grow; for when these plants are in a vigorous state, they will spread eight or ten feet; so that if they are confined, they will become so thick, as to rot the tender branches which are covered from the air, and there will be no fruit produced.

The fruit, when it is young, is by some people eaten, and made into Mangoes, and preserved in pickle; but it hath a very disagreeable taste, and is not accounted very wholesome: wherefore these plants are seldom cultivated in Europe, except by such persons as are curious in botany, for variety.

LUNARIA. Tourn. Inst. R. H. 218. tab. 105. Gen. Plant. 725. [so called of Luna, Lat. the moon. because the seed-vessels resemble the form of the moon.] Moonwort, Sattin Flower, or Honesty; in French, *Bulbonac*.

The CHARACTERS are,

The empalement of the flower is composed of four oblong, oval, small leaves, which are obtuse and fall off; the flower has four petals in form of a cross, which are large, obtuse, and entire: it hath six awl-shaped stamina, four of these are the length of the empalement; the other two are shorter, terminated by erect summits. It has an oblong oval germen sitting upon a small foot-stalk, supporting a short style, crowned by an entire obtuse stigma. The germen afterward becomes an erect, plain, compressed, elliptical pod, sitting upon the small foot-stalk, terminated by the style, having two cells opening with two valves, which are parallel, inclosing several compressed kidney-shaped seeds, which are bordered, sitting in the middle of the pod.

L U N

This genus of plants is ranged in the second section of Linnæus fifteenth class, intitled *Tetradynamia filiculosa*, which includes those plants whose flowers have four long and two shorter stamina, and the seeds are included in short pods.

The SPECIES are,

1. LUNARIA (*Rediviva*) *filiculis oblongis*. Lin. Sp. Plant. 653. *Sattin Flower with oblong pods*. Lunaria major, *siliqua longiore*. J. B. 2. 881. *Greater Moonwort with longer pods, commonly called Honesty, or White Sattin*.
2. LUNARIA (*Annuæ*) *filiculis subrotundis*. Lin. Sp. Plant. 653. *Sattin Flower with roundish pods*. Lunaria major, *siliqua rotundiore*. J. B. *Greater Moonwort with a rounder pod*.
3. LUNARIA (*Ægyptiaca*) *foliis supra decompositis, foliolis trifidis, filiculis oblongis pendulis*. *Moonwort with leaves decomposed whose lobes are trifid, and oblong hanging pods*. *Cardamine foliis supra decompositis, siliquis unilocularibus pendulis*. Lin. Sp. Plant. 656. *Lady's Smock with leaves decomposed above, and hanging pods containing one cell*.
4. LUNARIA (*Perennis*) *perennis, filiculis oblongis, foliis lanceolatis incanis*. *Perennial Moonwort, with oblong pods and spear-shaped hoary leaves*. Lunaria perennis, *lutea, folio leucoli, ramis expansis*. Vaill. *Yellow perennial Moonwort, with a Stock Gilliflower leaf and expanded branches*.

The first sort grows naturally in Hungary, Istria, and Austria, but has been long an inhabitant of the English gardens. It is a biennial plant, which perishes soon after the seeds are ripe; it rises with a branching stalk from two to three feet high, covered with a reddish hairy bark, sending out branches on every side from the ground upward; these are garnished with heart-shaped leaves placed alternately, ending in acute points indented on their edges, and are a little hairy; the lower standing upon pretty long foot-stalks, but the upper sit close to the branches. The flowers are produced at the top and from the side of the branches toward their ends, in clusters; they are composed of four purplish heart-shaped petals, placed in form of a cross. These appear in May, and are succeeded by large flat roundish pods with two cells, inclosing two rows of flat kidney-shaped seeds, which have a border round them. These pods, when ripe, turn to a clear white or sattin colour, from whence the title of Sattin Flower has been given to it, and are transparent.

The seed-vessels of this plant, when they are full ripe, become very transparent, and of the appearance of white sattin, at which time the branches are cut off and dried; after which they are preserved to place in the chimneys of halls and large rooms, where they continue a long time in beauty.

This is propagated by seeds, which should be sown in the autumn; for those which are sown in the spring often miscarry, or lie a long time in the ground before they appear. The plants will grow in almost any soil, but love a shady situation; it requires no other culture, but to keep it clean from weeds. If the seeds are permitted to scatter, the plants will rise without any farther care; and if they are left unmoved, they will grow much larger than those which are transplanted; the roots of this sort perish soon after the seeds are ripe.

The second sort grows naturally upon the mountains in Italy; this hath stalks and leaves very like the first, but the flowers are rather larger, and of a lighter purple colour; but the principal difference is in the pods of this being longer and narrower than those of the other. It flowers and feeds at the same time with the first, and requires the same culture.

The third sort is an annual plant, which grows naturally in Egypt. This rises with a smooth branching stalk little more than a foot high, garnished with winged leaves, composed of several pair of lobes ranged along the midrib, terminated by an odd one; these lobes are of unequal sizes, and vary in their form; some of them are almost entire, and others are cut at their extremities into three parts; they are

L U P

smooth, and of a lucid green. The flowers stand each upon pretty long slender foot-stalks, which come out from the side, and also at the end of the branches, in loose small clusters; they are of a purple colour, and are succeeded by oblong compressed pods, which hang downward. This sort flowers in June and July, the seeds ripen the beginning of September, and the plants decay soon after.

This is propagated by seeds, which should be sown upon an open border where the plants are to remain; if they are sown soon after they are ripe, the plants will come up in the autumn, and live through the winter in a sheltered situation; these will flower early the following summer, whereby ripe seeds may be obtained; they may also be sown in the spring in like manner. When the plants come up, they will require no other care but to keep them clean from weeds, and thin them where they are too close. If the seeds are permitted to scatter in the autumn, the plants will rise without care, and may be treated in the same way, which is much preferable to the sowing the seeds in the spring.

The fourth sort grows naturally in the Archipelago; this hath a perennial root, from which arise two or three ligneous stalks a foot high, covered with a white hairy bark, dividing upward into several smaller branches, garnished with spear-shaped leaves sitting close to the stalks, which are a little hoary. The branches are terminated by loose spikes of yellow flowers which appear in June, and are succeeded by oblong flat pods, containing flat kidney-shaped seeds, which ripen in the autumn.

This sort is propagated by seeds, which, if sown in the autumn, will succeed better than in the spring; they should be sown on a warm border, and on a dry poor soil, otherwise they will not live through the winter; but in a rubbishy soil the plants will continue two or three years.

LUPINUS. Tourn. Inst. R. H. 392. tab. 213. Lin. Gen. Plant. 774. Lupine; in French, *Lupin*.

The CHARACTERS are,

The empalement is bifid and of one leaf; the flower is of the butterfly kind; the standard is roundish, heart-shaped, indented at the top, and the sides reflexed and compressed. The wings are nearly oval, and almost as long as the standard; they are not fixed to the keel, but close at their base; the keel is as long as the wings, but is narrow, falcated, and ends in a point. It hath ten stamina joined at their base in two bodies, but as they rise are distinct above, terminated by five oblong summits. In the center is situated a hairy, compressed, awl-shaped germen, supporting a rising style, terminated by an obtuse stigma. The germen afterward becomes a large, oblong, thick pod with one cell, ending with an acute point, including several roundish compressed seeds.

This genus of plants is ranged in the third section of Linnæus's seventeenth class, intitled *Diadelphia Decandria*, which includes those plants whose flowers have ten stamina joined in two bodies.

The SPECIES are,

1. LUPINUS (*Varius*) *calycibus semiverticillatis appendiculatis, labio superiore bifido, inferiore subtridentato*. Hort. Cliff. 499. *Lupine with empalements half whorled, having appendages, whose upper lip is bifid, and the under one almost trifid*. Lupinus sylvestris, *purpureo flore, semine rotundo vario*. J. B. 2. 291. *Wild Lupine, with a purple flower and a round variegated seed, commonly called the lesser blue Lupine*.
2. LUPINUS (*Angustifolius*) *calycibus verticillatis appendiculatis, labio superiore bipartito, inferiore integro*. Lin. Sp. Plant. 721. *Lupine with empalements having alternate appendages, whose upper lip is divided into two, and the under one entire*. Lupinus angustifolius *cœruleus clatior*. Raii Hist. 908. *Narrow-leaved taller blue Lupine*.
3. LUPINUS (*Luteus*) *calycibus verticillatis appendiculatis, labio superiore bipartito, inferiore tridentato*. Hort. Cliff. 499. *Lupine with empalements growing in whorls, having appendages to them, whose upper lips are cut into two parts, and the under one into three*. Lupinus sylvestris, *flore luteo*. C. B. P. 348. *The common yellow Lupine*.

4. Lu-

4. LUPINUS (*Elirsutis*) calycibus verticillatis appendiculatis, labio superiore inferioreque integris. Hort. Cliff. 499. *Lupine with whorl-shaped empalements having appendages, and the upper and under lip entire.* Lupinus peregrinus major, vel villosus, cœruleus, major. C. B. P. *Foreign, greater, hairy Lupine, with a large blue flower, commonly called the great blue Lupine.*
5. LUPINUS (*Albus*) calycibus alternis inappendiculatis, labio superiore integro, inferiore tridentato. Hort. Cliff. 499. *Lupine with alternate empalements having no appendages, and the upper lip entire, but the under cut into three parts.* Lupinus sativus, flore albo. C. B. P. 347. *Garden or manured Lupine, with a white flower.*
6. LUPINUS (*Perennis*) calycibus alternis inappendiculatis, labio superiore emarginato, inferiore integro. Lin. Sp. Plant. 721. *Lupine with alternate empalements having no appendages, the upper lip indented, and the under entire.* Lupinus cœruleus, minor, perennis, Virginianus, repens. Mor. Hist. 2. p. 87. *Smaller perennial, creeping, blue Lupine of Virginia.*

The first sort grows naturally among the Corn in the south of France and Italy, and in great abundance in Sicily. This is an annual plant, which rises with a firm, strait, channelled stalk near three feet high, divided toward the top into several branches, which are garnished with hand-shaped leaves, composed of five, six, or seven oblong lobes, which join in one center at their base, and are hairy. The flowers are produced in spikes at the end of the branches, standing half round the stalk in sort of whorls; they are of a light blue colour, shaped like those of Peas, and are succeeded by strait taper pods with one cell, inclosing a row of roundish seeds. This sort flowers in June and July, and the seeds ripen in the autumn.

It is propagated in the borders of the pleasure-garden for ornament, by sowing the seeds in April, in the places where they are to remain; and when the plants come up they should be thinned where they are too close, and kept clean from weeds, which is all the culture they require.

The second sort has much the appearance of the first, but the stalks rise higher; the leaves have more lobes, and stand upon longer foot-stalks; the lobes are blunt-pointed, and the seeds are variegated. This requires the same culture as the first, and flowers at the same time.

The third sort is the common yellow Lupine, which has been long cultivated in the English gardens for the sweetness of its flowers. This grows naturally in Sicily; it rises about a foot high, with a branching stalk garnished with hand-shaped leaves, composed of nine narrow hairy lobes, which join at their base to the foot-stalks; these are four or five inches long. The flowers are yellow, and are produced in loose spikes at the end of the branches, standing in whorls round the stalks, with spaces between them, terminated by three or four flowers, sitting close at the top; these are succeeded by flattish hairy pods about two inches long, standing erect, inclosing four or five roundish seeds, a little compressed on their side, of a yellowish white, variegated with dark spots. This sort flowers at the same time as the former, but to have a succession of the flowers, the seeds are sown at different times, viz. in April, May, and June; but those only, which are first sown, will ripen their seeds. It may be cultivated in the same manner as the two former, and is equally hardy.

The fourth sort is supposed to be a native of India, but has been many years in the English gardens. It is an annual plant, which rises with a strong, firm, channelled stalk from three to four feet high, covered with a soft brownish down, dividing upward into several strong branches, garnished with hand-shaped leaves, composed of nine, ten, or eleven wedge-shaped hairy lobes, which are narrow at their base where they join the foot-stalk, but enlarge upward, and are rounded at the top where they are broadest; the foot-stalks of the leaves are three or four inches long. The flowers are placed in whorls round the stalks above each other, forming a loose spike, which

proceeds from the end of the branches; they are large, and of a beautiful blue colour, but have no scent. These appear in July, and the seeds ripen in the autumn. The pods of this sort are large, almost an inch broad, and three inches long, inclosing three large roundish seeds compressed on their sides, very rough, and of a purplish brown colour. There is a variety of this with flesh-coloured flowers, which is commonly called the Rose Lupine; it differs from the blue only in the colour of the flower, but this difference is permanent, for neither of the sorts vary.

This is generally late in ripening the seeds, so that unless the autumn proves warm and dry, they do not ripen; therefore the best way to have good seeds, is to sow them in September close to a warm wall on dry ground, where they will live through our ordinary winters; and these plants will flower early the following summer, so there will be time for the seeds to ripen before the rains fall in the autumn, which frequently causes the seeds to rot which are not ripe. If a few of the seeds of both these varieties are sown in small pots the beginning of September, and when the frosts begin, the pots are removed into a common hot-bed frame, where they may be protected from hard frost, but enjoy the free air in mild weather, the plants may be thus secured in winter; and in the spring they may be shaken out of the pots, preserving the earth to their roots, and planted in a warm border, where they will flower early, and produce very good seeds.

The fifth sort grows naturally in the Levant, but is cultivated in some parts of Italy, as other pulse, for food. This hath a thick upright stalk about two feet high, which divides toward the top into several smaller hairy branches, garnished with hand-shaped leaves, composed of seven or eight narrow oblong lobes, which are hairy, and join at their base, of a dark grayish colour, and have a silvery down. The flowers are produced in loose spikes at the end of the branches; they are white, and sit close to the stalk; these are succeeded by hairy strait pods about three inches long, a little compressed on the sides, containing five or six flattish seeds which are white, having a little cavity like a navel, in that part which is fixed to the pod. This sort flowers in July, and the seeds ripen in the autumn. It is an annual plant, which is cultivated for ornament in the pleasure-garden. The seeds must be sown in the places where the plants are to remain, and may be treated in the same way as the first sort.

The sixth sort grows naturally in Virginia, and other of the northern parts of America. This hath a perennial creeping root, from which arise several erect channelled stalks a foot and a half high, sending out two or three small side branches, garnished with hand-shaped leaves, composed of ten or eleven narrow spear-shaped lobes, which join at their base, standing upon very long foot-stalks, having a few hairs on their edges. The flowers grow in long loose spikes, which terminate the stalks, and are placed without order on each side; they are of a pale blue colour, having short foot-stalks. These appear in June, and the seeds ripen in August, which are soon scattered if they are not gathered when ripe; for after a little moisture, the sun causes the pods to open with an elasticity, and cast out the seeds to a distance all round. This sort is propagated by seeds as the former, which should be sown where the plants are to remain; for although the root is perennial, yet it runs so deep into the ground as that it cannot be taken up entire; and if the root is cut or broken, the plant seldom thrives well after. I have traced some of the roots of this plant, which have been three feet deep in the ground in one year from seed, and spread out as far on every side, so that they must have room, therefore the young plants should not be left nearer than three feet asunder. If this plant is in a light dry soil, the roots will continue several years, and produce many spikes of flowers; and although the usual season of flowering is in June and July,

L U P

July, yet when rain happens to fall in August, there are frequently fresh stalks arise from the roots, which flower the end of September, or beginning of October.

The seeds of the fifth sort are used in medicine; they have a bitter taste, so open, digest, dissolve, and cleanse; and if they are steeped in water for some days, till they have lost their bitterness, they may be eaten out of necessity, but they are supposed to breed gross humours, and are hard of digestion. Some women use the flower of the seed mixed with the juice of Lemons, and a little Alumen saccharinum, made into the form of soft ointment, to make the face smooth, and look more amiable.

The small blue Lupine is frequently sown in Italy, to dress and manure the ground, especially that which is intended for vineyards; where, if they have time, the ground is sown with Lupines, which grow till they begin to flower; then they cut them down and plough them into the ground, where the stalks rot with the winter's rain; but it is doubtful whether this is any real benefit to the ground, for there are few plants which draw and impoverish the ground so much as Lupines; therefore the dressing they yield, is scarce an equivalent for what they have drawn from the ground: but when there is not time for this operation, they parboil the seeds to prevent their growing, and sow them upon the ground before it is ploughed, allowing sixteen bushels to an acre of land; and this dressing is preferable to the former.

All the sorts of Lupines make a pretty appearance when they are in flower, but the yellow sort is preferred for its sweetness, though the flowers of this are of short duration, especially in warm weather; therefore the seeds of this should be sown at several times, that there may be a succession of flowers through the season, for they will continue flowering till they are stopped by hard frost; and those which come in the autumn to flower, will continue in beauty a longer time than the early ones. If some of the seeds are sown in the autumn on a warm border, the plants will often live through the winter, and flower early in the spring.

LUPULUS. Tourn. Inst. R. H. 535. tab. 309. Humulus. Lin. Gen. Plant. 989. [This plant takes its name of Lupus, *Lat.* a wolf, because the antients had a notion, that wolves were wont to hide themselves under this plant.] The Hop; in French, *Houblon*.

The CHARACTERS are,

The male and female flowers are upon different plants. The empalement of the male flower is composed of five small, concave, obtuse leaves; it hath no petal, but has five short hairy stamina, terminated by oblong summits. The female flowers have a general, four-pointed, acute perianthium, and a separate oval one of four leaves, including eight flowers; each of these have an empalement of one leaf, which is closed at the base. These have neither petal or stamina, but a small germen situated in the center, supporting two awl-shaped styles, crowned by acute, reflexed, spreading stigmas. The germen afterward turns to a roundish seed covered with a thin skin, inclosed in the base of the empalement.

This genus of plants is ranged in the fifth section of Linnæus's twenty-second class, intitled Diœcia Pentandria, which includes those plants whose male and female flowers are upon different plants, and the male flowers have five stamina.

We have but one SPECIES of this genus, viz.

LUPULUS (*Humulus*) mas & femina. C. B. P. 298. *Male and female Hop.*

The male Hop grows wild by the side of hedges and upon banks, in many parts of England: the young shoots of these plants are often gathered in the spring by the poor people, and boiled as an esculent herb; but these must be taken very young, otherwise they are tough and stringy; it is easily distinguished by the flowers, which are small, and hang in long loose bunches from the side of the stalks, abound-

L U P

ing with farina on their summits; these have no Hops succeeding to the flowers.

The female Hop is the sort which is cultivated for use; of this sort, the people who cultivate them reckon three different varieties: as first, the long and square Garlick Hop, the long white Hop, and the oval Hop, all which are indifferently cultivated in England, but of the male Hop there is no different varieties.

There being the greatest plantation of Hops in Kent that are in any county of England, it is very probable, that their method of planting and ordering them should be the best.

As for the choice of their Hop-grounds, they esteem the richest and strongest grounds as the most proper; they chuse a warm dry soil, that has a good depth of hazel mould; and if it be rocky within two or three feet of the surface, the Hops will prosper well; but they will by no means thrive on a stiff clay, or spongy wet land.

If it may be, chuse a piece of meadow or lay ground to plant Hops on, such as has not been tilled or sown with other crops for many years, or an old decayed orchard; for land that is worn out by long bearing of Corn, will require abundance of dung to bring it into any tolerable condition to bear a crop of Hops. The Kentish planters accounting new land best for Hops, they plant their Hop-gardens with Apple-trees at a large distance, and with Cherry-trees between; and when the land hath done its best for Hops, which they reckon it will in about ten years, the trees may begin to bear. The Cherry-trees last about thirty years, and by that time the Apple-trees are large, they cut down the Cherry-trees.

The Essex planters account a moory land the properest for Hops, though there are several other sorts of soil that are esteemed very good.

Some account that land which has a rosselly top, and a brick earth bottom, the best; a true rossel or light sand, is what they generally plant in, whether it be white or black.

Moory land is of different sorts, some being strong and heavy, so as to crack in summer; and some so light, that in dry seasons it will blow away with the wind; and some are of a middle consistence, being composed of both.

These moors for goodness and value, are according to the nature and goodness of the soil that is underneath them; which being flung up upon the surface, will make a very good mixture, it being best to fling the under soil downward for Hops, because they naturally root downwards, sometimes four or five yards deep, and therefore the deepest and richest soil is best for them.

Few are acquainted with the value of moors, because they do not search into the bottom of them, by reason of the expensiveness of doing it, and the difficulty of carrying off the water.

If the land be moist, it ought to be laid up in high ridges, and to be well drained, and the drains kept clear and open, especially in winter, that the water do not rot or too much chill the roots.

If the land be sour or cold, it will be very much helped by burning it; and if the haulm and strings of the Hops be burnt every year, and some of the paring or sides of the garden or other earth be laid on them as they burn, and then more haulm be laid over that, and so continued layer upon layer, it will make an excellent compost to make the hills with.

As to the situation of a Hop-ground, one that inclines to the south or west is the most eligible; but if it be exposed to the north-east or south-west winds, there should be a center of some trees at a distance; because the north-east are apt to nip the tender shoots in the spring, and the south-west frequently break and blow the poles at the latter end of the summer, and very much endanger the Hops.

Hops require to be planted in an open situation, that the air may freely pass round and between them to dry up and dissipate the moisture, whereby they will not be

be so subject to fire blasts, which often destroy the middles of large plantations, while the outsidcs remain unhurt.

As for the preparation of the ground for planting, it should, the winter before, be ploughed and harrowed even; and then lay upon it in heaps a good quantity of fresh rich earth, or well rotted dung and earth mixed together, sufficient to put half a bushel in every hole to plant the Hops in, unless the natural ground be very fresh and good.

Then lay a line across it from the hedge, in which knots have been tied, at the distance you design your Hop-hills to be at, about eight or nine feet distance the whole length of the ground, and place a sharp pointed stick at every knot; then lay aside the line, and with two forked sticks of about eight or nine feet long, you may from the first row set out the whole ground, by applying the two forks to two of the sticks which were first set up, and placing another row at the ends, where the forked sticks meet triangular-wise; then you should dig a hole at every stick about a foot and a half wide, and fill it full of the good earth you brought in.

If you plough the ground with horses between the hills, it will be best to plant them in squares chequer-wise; but the quincunx form is the most beautiful, and it will also be better for the Hop; but if the ground is intended to be cultivated by the breast-plough, it will be best to plant them in squares; but which way soever you make use of, a stake should be stuck down at all the places where the hills are to be made.

Persons ought to be very curious in the choice of the plants and sets, as to the kind of the Hop; for if the Hop-garden be planted with a mixture of two or three sorts of Hops that ripen at different times, it will cause a great deal of trouble, and be a great detriment to the owner.

The two best sorts are the white and the gray bind; the latter is a large square Hop, more hardy, and is the more plentiful bearer, but ripens later than the former.

There is also another sort of the white bind, which ripens in a week or ten days before the common; but this is tenderer, and a less plentiful bearer, but it has this advantage, it comes first to market.

But if three grounds, or three distant parts of one ground, be planted with these three sorts, there will be this conveniency, that they may be picked successively as they become ripe.

The sets ought to be procured out of grounds that are entirely of the same sort you would have, they should be five or six inches long, with three or more joints or buds on them, all the old bind and hollow part of the set being cut off.

If there be a sort of Hop you value, and would increase plants and sets from, the superfluous binds may be laid down when the Hops are tied, cutting off the tops, and burying them in the hill; or when the Hops are dressed, all the cuttings may be saved, and laid in rows in a bed of good earth; for almost every part will grow, and become a good set the next spring.

Some have tried to raise a Hop-ground by sowing seeds, but that turns to no account, because that way is not only tedious, but the Hops so produced are commonly of different kinds, and many of them wild and barren.

As to the seasons of planting Hops, the Kentish planters best approve the months of October and March, both which succeed very well; but the common sets are not to be had in October, unless from some ground that is to be digged up and destroyed; and likewise there is some danger that the sets may be rotted, if the winter prove very wet; but the most usual time of procuring them is in March, when the Hops are cut and dressed.

As to the manner of planting the sets, you should put two or three good sets in every hole with a setting stick, at about four inches distance, placing them sloping; they must stand even with the surface of the

ground; let them be pressed close with the hand, and covered with fine earth, and a stick should be placed on each side the hill to secure it.

The ground being thus planted, all that is to be done more than summer, is to keep the hills clear from weeds, and to horse-hoe the ground about the month of May, gathering up the stones, if more are turned up by ploughing, and to raise a small hill round about the plants; and in June you must twist the young binds or branches together in a bunch or knot, for if they are tied up to small poles the first year, in order to have a few Hops from them, it will not countervail the weakening the plants.

A mixture of compost or dung being prepared for your Hop-ground, the best time for laying it on, if the weather prove dry, is about Michaelmas, that the wheels of the dung-cart may not injure the Hops, nor furrow the ground: if this be not done then, you must be obliged to wait till the frost has hardened the ground, so that it will bear the dung-cart; and this is also the time to carry on your new poles, to recruit those that are decayed, and to be cast out every year.

If you have good store of dung, the best way will be to spread it in the alleys all over the ground, and to dig or plough it in the winter following. The quantity they will require, will be forty loads to an acre, reckoning about thirty bushels to the load.

If you have not dung enough to cover all the ground in one year, you may lay it on one part one year, and on the rest in another, or a third; for there is no occasion to dung the ground after this manner, oftener than once in two or three years.

Those who have but a small quantity of dung, usually content themselves with laying on about twenty loads upon an acre every year; this they lay only on the hills, either about November, or in the spring; which last some account the best time, when the Hops are dressed, to cover them after they are cut; but if it be done at this time, the compost or dung ought to be very well rotted and fine.

As to the dressing of the Hops, when the Hop-ground is dug or ploughed in January or February, the earth about the hills, and very near them, ought to be taken away with a spade, that you may come the more conveniently at the stock to cut it.

About the end of February, if the Hops were planted the spring before, or if the ground be weak, they ought to be dressed in dry weather; but else, if the ground be strong and in perfection, the middle of March will be a good time; and the latter end of March, if it be apt to produce over rank binds, or the beginning of April, may be soon enough.

Then having with an iron picker cleared away all the earth out of the hills, so as to make the stock bear to the principal roots, with a sharp knife you must cut off all the shoots which grew up with the binds the last year; and also all the young suckers, that none be left to run in the alley and weaken the hill. It will be proper to cut one part of the stock lower than the other, and also to cut that part low, that was left highest the preceding year. By pursuing this method, you may expect to have stronger buds, and also keep the hill in good order.

In dressing those Hops that have been planted the year before, you ought to cut off both the dead tops, and the young suckers which have sprung up from the sets, and also to cover the stocks with fine earth a finger's length in thickness.

About the middle of April the Hops are to be polled, when the shoots begin to sprout up; the poles must be set to the hills deep into the ground, with a square iron pitcher or crow, that they may the better endure the wind; three poles are sufficient for one hill. These should be placed as near the hills as may be, with their bending tops turned outwards from the hill, to prevent the binds from entangling; and a space between two poles ought to be left open to the south, to admit the sun beams.

The poles ought to be in length sixteen or twenty feet, more or less, according as the ground is in

strength; and great care is to be taken not to over-pole a young or weak ground, for that will draw the stock too much, and weaken it. If a ground be over-poled, you are not to expect a good crop from it; for the branches which bear the Hops will grow very little, till the binds have over-reached the poles, which they cannot do when the poles are too long. Two small poles are sufficient for a ground that is young.

If you wait till the sprouts or young binds are grown to the length of a foot, you will be able to make a better judgement where to place the largest poles; but if you stay till they are so long as to fall into the alleys, it will be injurious to them, because they will entangle one with another, and will not clasp about the pole so readily.

Maple or Aspen poles are accounted the best for Hops, on which they are thought to prosper best, because of their warmth; or else, because the climbing of the Hop is furthered by means of the roughness of the bark. But for lastingness, Ashen or Willow poles are preferable; but Chestnut poles are the most durable of all.

If, after the Hops are grown up, you find any of them have been under-poled, taller poles may be placed near those that are too short, to receive the binds from them.

As to the tying of Hops, the buds that do not clasp of themselves to the nearest pole when they are grown to three or four feet high, must be guided to it by the hand, turning them to the sun, whose course they will always follow. They must be bound with withered Rushes, but not so close as to hinder them from climbing up the pole.

This you must continue to do till all the poles are furnished with binds, of which two or three are enough for a pole; and all the sprouts and binds that you have no occasion for, are to be plucked up; but if the ground be young, then none of these useless binds should be plucked up, but should be wrapt up together in the middle of the hill.

When the binds are grown beyond the reach of your hands, if they forsake the poles, you should make use of a stand ladder in tying them up.

Some advise, that if the binds be very strong, and overgrow the poles very much, you strike off their heads with a long switch, to increase their branching below.

Towards the latter end of May, when you have made an end of tying them, the ground must have the summer ploughing or digging, which is done by casting up with the spade some fine earth into every hill, and a month after it must be again repeated, and the hills made up to a convenient bigness.

It is not at all to be doubted, but that a thorough watering would be of very great advantage to Hops in a hot dry summer; but it is so much charge and trouble to do this, that unless you have a stream at hand to flow the ground, it is scarce practicable.

When the Hops blow, you should observe if there be any wild barren hills among them, and mark them, by driving a sharpened stick into every such hill, that they may be dug up and replanted.

Hops as well as other vegetables, are liable to distempers and disasters, and among the rest, to the fen. The Rev. Dr. Hales, in his excellent Treatise of Vegetable Statics, treating of Hops, gives us the following account of the state of Hops in Kent in the year 1725, that he received from Mr. Austen of Canterbury, which is as follows:

In mid April not half the shoots appeared above ground, so that the planters knew not how to pole them to the best advantage.

This defect of the shoot, upon opening the hills, was found to be owing to the multitude and variety of vermin that lay preying upon the roots; the increase of which, was imputed to the long and almost uninterrupted series of dry weather for three months before. Towards the end of April many of the Hop-vines were infested with flies.

About the 20th of May there was a very unequal appearance, some Vines being run seven feet, others not above three or four; some just tied to the poles, and some not visible; and this disproportionate inequality in their size, continued through the whole time of their growth.

The flies now appeared upon the leaves of the forwardest Vines, but not in such numbers here, as they did in most other places. About the middle of June the flies increased, yet not so as to endanger the crop; but in distant plantations they were exceedingly multiplied, so as to swarm towards the end of the month.

June the 27th some specks of fen appeared. From this day to the 9th of July was very dry weather. At this time, when it was said, that the Hops in most parts of the kingdom looked black and sickly, and seemed past recovery, ours held it out pretty well, in the opinion of the most skilful planters.

The great leaves were indeed discoloured, and a little withered, and the fen was somewhat increased. From the 9th of July to the 23d, the fen increased a great deal; but the flies and lice decreased, it raining much daily. In a week more the fen, which seemed to be almost at a stand, was considerably increased, especially in those grounds where it first appeared.

About the middle of August the Vines had done growing both in stem and branch, and the forwardest began to be in the Hop, the rest in bloom; the fen continued spreading where it was not before perceived, and not only the leaves, but many of the burs were also tainted with it.

About the 20th of August some of the Hops were infested with the fen, and whole branches corrupted by it. Half the plantations had pretty well escaped hitherto, and from this time the fen increased but little; but several days wind and rain the following week so distorted them, that many of them began to dwindle, and at last came to nothing; and of those that then remained in bloom, some never turned to Hops; and of the rest which did, many of them were so small, that they very little exceeded the bigness of a good thriving bur.

We did not begin to pick till the 8th of September, which is eighteen days later than we began the year before; the crop was little above two hundred on an acre round, and not good. The best Hops sold this year at Way-hill, for 161. the hundred.

The Rev. Dr. Hales, in his aforesaid Treatise, gives us an account of the following experiment that he made on Hop-vines. He tells us, that in July he cut off two thriving Hop-vines near the ground, in a thick shady part of the garden, the pole still standing; he stripped the leaves off from one of these Vines, and set their stems in known quantities of water in little bottles; that with leaves imbibed in a twelve hours day four ounces, and that without leaves three-fourths of an ounce.

He took another Hop-pole with its Vines on it, and carried it out of the Hop-ground into a free and open exposure; these imbibed and perspired as much more as the former in the Hop-ground, which is, doubtless, the reason why the Hop-vines on the outsides of plantations, where they are most exposed to the air, are short and poor, in comparison of those in the middle of the ground, viz. because being much dried, their fibres harden sooner, and therefore they cannot grow so kindly as those in the middle of the ground, which, by shade, are always kept moister, and more ductile.

The same curious author proceeds as followeth: Now there being 1000 hills in an acre of Hop-ground, and each hill having three poles, and each pole three Vines, the number of Vines will be 9000, each of which perspiring four ounces, the sum of all the ounces perspired by an acre in twelve hours day will be 36000 ounces = 15750000 grains = 62007 cube inches, or 220 gallons, which divided by 6272640, the number of square inches in an acre, it will be found, that the quantity of liquor perspired by all the Hop-vines will be equal to an area of liquor as broad as an acre, and

part of an inch deep, besides what evaporated from the earth.

And this quantity of moisture, in a kindly state of the air, if daily carried off, is a sufficient quantity to keep the Hops in a healthy state; but in a rainy moist state of air, without a due mixture of dry weather, too much moisture hovers about the Hops, so as to hinder, in some measure, the kindly perspiration of the leaves, whereby the stagnating sap corrupts, and breeds mouldy fen, which often spoils vast quantities of flourishing Hop-grounds.

This was the case in the year 1723, when for ten or fourteen days almost continual rains fell, about the latter half of July, after four months dry weather, upon which the most flourishing and promising Hops were all infected with mould, or fen, in their leaves and fruit, while the then poor and unpromising Hops escaped, and produced plenty, because they, being small, did not perspire so great a quantity as others, nor did they confine the perspired vapour, so much as the large thriving Vines did in their shady thickers.

This rain on the then warm earth, made the Grass shoot out as fast as if it were in a hot-bed, and the Apples grew so precipitately, that they were of a fleshy constitution, so as to rot more remarkably than had ever been remembered.

The planters observe, That when a mould, or fen, has once seized any part of the ground, it soon runs over the whole, and that the Grass, and other herbs under the Hops, are infected with it, probably, because the small seeds of this quick-growing mould, which soon come to maturity, are blown over the whole ground; which spreading of the seed may be the reason why some grounds are infected with fen for several years successively, viz. from the seeds of the last year's fen. Might it not then be advised to burn the fenny Hop-vines, as soon as the Hops are picked, in hopes thereby to destroy some of the seed of the mould?

Mr. Austen, of Canterbury, observes fen to be more fatal to those grounds that are low and sheltered, than to the high and open grounds, to those that are shelving to the north, than to those shelving to the south; to the middle of grounds than to the outsides; to the dry and gentle grounds, than to the moist and stiff grounds.

This was very apparent throughout the plantations where the land had the same workmanship and help bestowed upon it, and was wrought at the same time. But if in either of these cases there was a difference, it had a different effect, and the low and gentle grounds, that lay neglected, were then seen less distempered than the open and moist, which were carefully managed and looked after.

The honey dews are observed to come about the 11th of June, which, by the middle of July, turn the leaves black, and make them stink.

The said Dr. Hales relates, That in the month of July (the season for fire-blasts, as the planters call them) he has seen the Vines in the middle of the Hop-ground scorched up almost from one end of a large ground to the other, when a hot gleam of sun-shine has come immediately after a shower of rain, at which time vapours are all seen with the naked eye, but especially with reflecting telescopes, to ascend so plentifully as to make a clear and distinct object become immediately very dim and tremulous; nor was there any dry gravelly vein in the ground along the course of this scorch; it was therefore, probably, owing to the much greater quantity of scorching vapours in the middle, than the outsides of the ground, and that being a denser medium, it was much hotter than a more rare medium.

And, perhaps, the great volume of ascending vapours might make the sun-beams converge a little towards the middle of the ground, that being a denser medium, and thereby increase the heat considerably; for he observed, That the course of the scorched Hops was in lines at right angles to the sun-beams about eleven o'clock, at which time the hot gleam was.

The Hop-ground was in a valley which ran from south-west to north-east, and to the best of his remembrance, there was but little wind, and that in the course of the scorch; but had there been some other gentle wind, either north or south, it is not improbable but that the north wind gently blowing the volume of rising wreak on the south side of the ground, that side might have been most scorched, and so vice versa.

As to particular fire-blasts, which scorch here and there a few Hop-vines, or one or two branches of a tree, without damaging the next adjoining, what astronomers observe, may hint to us no very improbable cause of it, viz. They frequently observe (especially with reflecting telescopes) small separate portions of pellucid vapours floating in the air, which, though not visible to the naked eye, are yet considerably denser than the circumambient air; and vapours of such a degree of density may very probably either acquire such a scalding heat from the sun as will scorch what plants they touch, especially the more tender.

(An effect which the gardeners about London have too often found to their cost, when they have incautiously put bell-glasses over their Cauliflowers early in a frosty morning, before the dew was evaporated off them; which dew, being raised by the sun's warmth, and confined within the glass, did there form a dense, transparent, scalding vapour, which burned and killed the plants:)

Or, perhaps, the upper or lower surface of these transparent, separate, flying volumes of vapours, may, among the many forms they revolve into, sometimes approach so near to an hemisphere, or hemicylinder, as thereby to make the sun-beams converge, so as often to scorch the more tender plants they shall fall on, and sometimes also parts of the more hardy plants and trees, in proportion to the greater or lesser convergency of the sun's rays.

The learned Boerhaave, in his Theory of Chymistry, p. 245, Shaw's edition, observes, That those white clouds which appear in summer time, are, as it were, so many mirrors, and occasion excessive heat. These cloudy mirrors are sometimes round, sometimes concave, polygonous, &c. When the face of heaven is covered with such white clouds, the sun shining among them, must, of necessity, produce a vehement heat, since many of his rays, which would otherwise, perhaps, never touch our earth, are hereby reflected to us. Thus, if the sun be on one side, and the clouds on the opposite one, they will be perfect burning-glasses, and hence the phenomena of thunder.

I have sometimes (continues he) observed a kind of hollow clouds full of hail and snow, during the continuance of which the heat was extreme, since, by such condensation, they were enabled to reflect more strongly. After this came a sharp cold, and then the clouds discharged their hail in great quantity, to which succeeded a moderate warmth. Frozen concave clouds, therefore, by their great reflexions, produce a vigorous heat, and the same, when resolved, excessive cold.

From which the Rev. Dr. Hales observes as follows: Hence we see, that blasts may be occasioned by the reflexions of the clouds, as well as by the above-mentioned refraction of dense transparent vapours.

About the middle of July Hops begin to blow, and will be ready to gather about Bartholomew-tide. A judgment may be made of their ripeness, by their strong scent, their hardness, and the brownish colour of their seed.

When by these tokens they appear to be ripe, they must be picked with all the expedition possible; for if at this time a storm of wind should come, it would do them great damage, by breaking the branches, and bruising and discolouring the Hops; and it is very well known, that Hops, being picked green and bright, will sell for a third part more than those which are discoloured and brown.

L U P

The most convenient way of picking them is into a long square frame of wood, called a bin, with a cloth hanging on tenter-hooks within it, to receive the Hops as they are picked.

The frame is composed of four pieces of wood joined together, supported by four legs, with a prop at each end to bear up another long piece of wood, placed at a convenient height over the middle of the bin; this serves to lay the poles upon which are to be picked.

This bin is commonly eight feet long, and three feet broad; two poles may be laid on it at a time, and six or eight persons may work at it, three or four on each side.

It will be best to begin to pick the Hops on the east or north side of your ground, if you can do it conveniently; this will prevent the south-west wind from breaking into the garden.

Having made choice of a plot of the ground containing eleven hills square, place the bin upon the hill which is in the center, having five hills on each side; and when these hills are picked, remove the bin into another piece of ground of the same extent, and so proceed till the whole Hop-ground is finished.

When the poles are drawn up to be picked, you must take great care not to cut the binds too near the hills, especially when the Hops are green, because it will make the sap to flow excessively.

And if the poles do not come up without difficulty, they should be raised by a piece of wood in the nature of a lever, having a forked piece of iron, with teeth on the inside, fastened within two feet of the end.

The Hops must be picked very clean, i. e. free from leaves and stalks, and, as there shall be occasion, two or three times in a day the bin must be emptied into a Hop-bag made of coarse linen cloth, and carried immediately to the oast, or kiln, in order to be dried; for if they should be long in the bin, or bag, they will be apt to heat, and be discoloured.

If the weather be hot, there should no more poles be drawn than can be picked in an hour, and they should be gathered in fair weather, if it can be, and when the Hops are dry; this will save some expence in firing, and preserve their colour better when they are dried.

The best method of drying Hops is with charcoal on an oast or kiln, covered with hair-cloth, of the same form and fashion that is used for drying malt. There is no need to give any particular directions for the making it, since every carpenter, or bricklayer, in those countries where Hops grow, or malt is made, knows how to build them.

The kiln ought to be square, and may be of ten, twelve, fourteen, or sixteen feet over at the top, where the Hops are laid, as your plantation requires, and your room will allow. There ought to be a due proportion between the height and breadth of the kiln, and the beguels of the steddle where the fire is kept, viz. if the kiln be twelve feet square on the top, it ought to be nine feet high from the fire, and the steddle ought to be six feet and a half square, and so proportionable in other dimensions.

The Hops must be spread even upon the oast a foot thick or more, if the depth of the curb will allow it, but care is to be taken not to overload the oast, if the Hops be green or wet.

The oast ought to be first warmed with a fire before the Hops are laid on, and then an even steady fire must be kept under them; it must not be too fierce at first, lest it scorch the Hops; nor must it be suffered to sink or slacken, but rather be increased till the Hops be near dried, lest the moisture, or sweat, which the fire has raised, fall back, or discolour them. When they have lain about nine hours, they must be turned, and in two or three hours more they may be taken off the oast. It may be known when they are well dried by the brittleness of the stalks, and the easy falling off of the Hop leaves.

The Dutch and Flemings have another method of drying their Hops: they make a square kiln, or room,

L U P

about eight or ten feet wide, built of brick or stone, having a door at one side, and a fire-place in the middle of the room, on the floor, about thirteen inches wide within, and thirteen inches high in length from the mouth of it, almost to the back part of the kiln, a passage being left just enough for a man to go round the end of it; this they call a horse, such as is commonly made in malt-kilns, the fire passing out at the holes at each side, and at the end of it.

The bed, or floor, on which the Hops lie to be dried, is placed about five feet high above; about that is a wall near four feet high, to keep the Hops from falling.

A window is made at one side of the upper bed, to shove off the dry Hops down into a room prepared to receive them. The beds are made of laths, or rails, sawn very even, lying a quarter of an inch distant from one another, with a cross beam in the middle, to support them; the laths are let in even with the top of the beam, and this keeps them even in the places; this they call an oast.

The Hops are laid on this bed by baskets full, without any oast-cloth, beginning at one end, and so going on till all is covered, half a yard thick, without treading them; then they even them with a rake, that they may lie of equal thickness.

This being done, they kindle the fire below, either of wood or charcoal, but the latter is accounted the better fuel for Hops; this fire is kept as much as may be at an equal or constant heat, and only at the mouth of the furnace, for the air will sufficiently disperse it.

They do not stir them till they are thoroughly dried, i. e. till the top is as fully dried as the bottom; but if they find any place not to be so dry as the rest, (which may be known by reaching over them with a stick or wand, and touching them in several places,) they observe where they do not rattle, and where they do; and where they do not rattle, they abate them there, and dispose of them where the places were first dry.

They know when they are thoroughly dry, by the brittleness of the inner stalk; if it be short when it is rubbed; which when they find, they take out the fire, and shove out the Hops at the window that is made for that purpose, into the room made to receive them, with a coal-rake made with a board at the end of a pole, and then go in at a door below, and sweep up the Hops and seeds that fall through, and put them to the other Hops; then they lay another bed of green Hops, and renew the fire, and proceed as before.

This method is disapproved by some, because (they say) the Hops lying so thick, and not being turned, the under part of them must needs dry before the upper; and the fire passing through the whole bed to dry the uppermost, must necessarily over-dry, and much prejudice the greatest part of the Hops, both in strength and weight, besides the unnecessary expence of firing, which must be long continued to dry thoroughly so many together.

Therefore some have improved on this method, and advised to make the kiln much as is before directed as to the Dutch way.

First to make a bed of flat ledges about an inch thick, and two or three inches broad, sawn, and laid across one another the flat way, chequerwise, at about three or four inches distance one from the other, the edges being so entered one into the other, that the floor may be even and smooth; this bed may be made to rest on two or three joists, set edgewise, to support it from sinking.

This bed is to be covered with large double tin, soldered together at each joint, and the ledges must be so ordered, before they are laid, that the joints of the tin may always lie over the middle of the ledge, the bed being wholly covered over with tin: boards must be fitted about the edges of the kiln, to keep up the Hops, but one side must be made to remove, that the Hops may be shoved off as before.

L U P

On this bed, or floor of tin, the Hops may be turned without such hazard or loss, as upon the hair-cloth: and also it will require a less expence of fuel, and, besides, any sort of fuel will serve in this kiln, as well as charcoal, because the smoke does not pass through the Hops as it does the former ways; but then care is to be taken, that there be passages made for it at the several corners and sides of the kiln.

It is found by experience, that the turning of Hops, though it be after the most easy and best manner, is not only an injury and waste to the Hops, but also an expence of fuel and time, because they require as much fuel, and as long a time, to dry a small quantity, by turning them, as a large one.

Now, this may be prevented, by having a cover (to be let down and raised at pleasure) to the upper bed whereon the Hops lie.

This cover may also be tinned, by nailing single tin plates over the face of it, so that when the Hops begin to dry, and are ready to burn, i. e. when the greatest part of their moisture is evaporated, then the cover may be let down within a foot, or less, of the Hops (like a reverberatory) and will reflect the heat upon them, so that the top will soon be as dry as the lowermost, and every Hop be equally dried.

As soon as the Hops are taken off the kiln, lay them in a room for three weeks or a month to cool, give, and toughen; for if they are bagged immediately, they will powder, but if they lie a while (and the longer they lie the better, provided they be covered close with blankets to secure them from the air,) they may be bagged with more safety, as not being liable to be broken to powder in treading, and this will make them bear treading the better, and the harder they are trodden, the better they will keep.

The common method of bagging is as follows; they have a hole made in an upper floor, either round or square, large enough to receive a Hop-bag (which consists of four ells and a half of ell-wide cloth, and also contains ordinarily two hundred and a half of Hops) they tie a handful of Hops in each lower corner of the bag, to serve as handles to it, and they fasten the mouth of the hole, so placed that the hoop may rest upon the edges of the hole.

Then he that is to tread the Hops down into the bag, treads the Hops on every side, another person continually putting them in as he treads them, till the bag is full, which being well filled and trodden, they unrip the fastening of the bag to the hoops, and let it down, and close up the mouth of the bag, tying up a handful of Hops in each corner of the mouth, as was done in the lower part.

Hops being thus packed, if they have been well dried, and laid up in a dry place, they will keep good several years; but care must be taken, that they be neither destroyed nor spoiled by the mice making their nests in them.

The crop of Hops being thus bestowed, you are to provide for another, first by taking care of the poles against another year, which are best to be laid up in a shed, having first stripped off the haulm from them; but if you have not that conveniency, set up three poles in the form of a triangle, or six poles (as you please) wide at the bottom, and having set them into the ground, with an iron pitcher, and bound them together at top, set the rest of your poles about them; and being thus disposed, none but those on the outside will be subject to the injuries of the weather, for all the inner poles will be kept dry, unless at the top; whereas, if they were on the ground, they would receive more damage in a fortnight, than by their standing all the rest of the year.

In the winter time provide your soil and manure for the Hop-ground against the following spring.

If the dung be rotten, mix it with two or three parts of common earth, and let it incorporate together till you have occasion to make use of it in making your Hop-hills; but if it be new dung, then let it be mixed as before, till the spring come twelvemonths, for new dung is very injurious to Hops.

L Y C

Dung of all sorts was formerly more commonly made use of than now it is, especially when rotted, and turned to mould, and they who have no other manure must use it; which, if they do, cows or hogs dung, or human ordure mixed with mud, may be a proper compost, because Hops delight most in a manure that is cool and moist.

Some recommend chalk, or lime, as the best manure, except in cold lands, and in such, pigeons dung will do best; a little of which laid to a hill, and so mixed, that it may not be too hot in a place, is of great advantage.

LUTEOLA. See **RESEDA**.

LYCHNIDEA. See **PHLOX**.

LYCHNIS. Tourn. Inst. R. H. 333. tab. 175. Lin. Gen. Plant. 517. [so called of *Λύχνος*, a candle, or light, because the flowers of this plant imitate the flame or rays of light.] **Campion**.

The **CHARACTERS** are,

The flower has a permanent swollen empalement of one leaf, indented in five parts at the top. It hath five petals, whose tails are the length of the empalement, their upper part plain, broad, and frequently cleft in laminae. It hath ten stamina which are longer than the empalement, alternately ranged, and fastened to the tails of the petals, terminated by prostrate summits. In the center is situated an almost oval germen, supporting five axel-shaped styles, crowned by reflexed hairy stigmas. The empalement afterward becomes an oval capsule with one cell, opening with five valves, filled with roundish seeds.

This genus of plants is ranged in the fifth section of Linnaeus's tenth class, intitled Decandria Pentagynia, which includes those plants whose flowers have ten stamina and five styles.

The **SPECIES** are;

1. **LYCHNIS** (*Chalcedonica*) floribus fasciculatis fastigiatis. Hort. Cliff. 174. *Campion with flowers gathered into a pyramid. Lychnis hirsuta, flore coccineo, major.* C. B. P. 203. *Greater hairy Campion with a scarlet flower.*
2. **LYCHNIS** (*Viscaria*) petalis integris. Lin. Sp. Plant. 436. *Campion with entire petals. Lychnis sylvestris viscosa, rubra, angustifolia.* C. B. P. 205. *Wild viscons Lychnis with a red flower and narrow leaves, commonly called the Single Catchfly.*
3. **LYCHNIS** (*Diæci*) floribus diæcis. Hort. Cliff. 171. *Campion with male and female flowers on different plants. Lychnis sylvestris, five aquatica purpurea; simplex.* C. B. P. 204. *Wood or aquatic Lychnis with a single purple flower, frequently called Bachelors Button.*
4. **LYCHNIS** (*Alba*) floribus diæcis, calycibus inflatis hirsutis. *Campion with male and female flowers growing on different plants, and swollen hairy empalements. Lychnis sylvestris, alba, simplex.* C. B. P. 204. *Wild campion with a single white flower.*
5. **LYCHNIS** (*Flosculi*) petalis quadrifidis, fructu subrotundo. Hort. Cliff. 174. *Campion with quadrifid petals, and a roundish fruit. Lychnis pratensis flore laciniato simplici.* Mor. Hist. 2. p. 537. *Meadow Campion with a single jagged flower, commonly called Ragged Robin.*
6. **LYCHNIS** (*Alpina*) petalis bifidis corymbosis. Lin. Sp. Plant. 436. *Campion with bifid petals, and flowers growing in a corymbus. Silene floribus in capitulum congestis.* Haller. Helv. 376. *Lychnis with flowers collected in a head.*
7. **LYCHNIS** (*Siberica*) petalis bifidis, caule dichotomo, foliis subhirsutis. Lin. Sp. Plant. 437. *Campion with bifid petals, a stalk divided by pairs, and leaves which are somewhat hairy.*

9. **LYCHNIS** (*Apetala*) calyce inflato, corollâ calyce brevior, caule subunifloro. Lin. Sp. Plant. 437. *Campion with a swollen empalement, the petals of the flower shorter than the cup, and stalks having chiefly one flower. Lychnis sylvestris alba, calyce amplo vestigio*

cario. Vaill. *Wild white Campion with a large inflated empalement.*

The first sort is commonly known by the title of Scarlet *Lychnis*; of which there is one with double flowers, which is most esteemed for the size of the flowers and multiplicity of the petals; as also for the duration of the flowers, which continue much longer in beauty than the single flowers, so that the latter is not much cultivated at present, though the flowers of this are very beautiful; and as the plants are so easily propagated by seed, they may soon be had in greater plenty than those with double flowers, which do not produce seeds. Of the single sort there are three varieties, the deep scarlet, the flesh-colour, and the white, but the first is the most beautiful.

This is easily propagated by seeds, which should be sown on a border exposed to the east, in the middle of March. The plants will appear in April, when if the season is dry, they should be refreshed with water two or three times a week. By the beginning of June the plants will be fit to remove, when there should be a bed of common earth prepared to receive them; into which they should be planted at about four inches apart, observing to water and shade them till they have taken root; after which time they will require no other care but to keep them clean from weeds till the following autumn, when they should be transplanted into the borders of the pleasure-garden, where they are to continue. The summer following these plants will flower and produce ripe seeds, but the roots will abide several years and continue to flower. This sort flowers in June and July, and the seeds ripen in autumn. It may also be propagated by offsets, but as the seeds ripen so freely, few persons trouble themselves to propagate the plants any other way. The French call this plant *Jerusalem Cross*.

The sort with double flowers is a valuable plant, the flowers are very double, and of a beautiful scarlet colour. This hath a perennial root, from which arise two, three, or four stalks, according to the strength of the roots; these in rich moist land, grow upwards of four feet high; the stalks are strong, erect, and hairy. They are garnished the whole length with spear-shaped leaves sitting close to the stalks, placed opposite; and just above each pair of leaves, there are four smaller leaves standing round the stalk. The flowers are produced in close clusters sitting upon the top of the stalk; when the roots are strong, the clusters of flowers will be very large, so they make a fine appearance, the flowers being very double, and of a bright scarlet colour. They appear the latter end of June, and in moderate seasons continue near a month in beauty. The stalks decay in autumn, and new ones arise in the spring. This was originally produced from the seeds of the single sort, and is propagated by slips taken from the roots in autumn; but as this is a slow method of increasing the plants, the best way to have them in plenty, is to cut off the flower-stalks in June before the flowers appear, which may be cut into small lengths, each of which should have three or four joints, which should be planted on an east border of soft loamy earth, putting three of the joints into the ground, leaving one eye just level with the surface; these must be watered, and then covered close with bell or hand-glasses, so as to exclude the outward air, and shaded with mats when the sun shines hot upon them. The cuttings so managed will put out roots in five or six weeks, when they must be exposed to the open air, and in very dry weather they should be now and then refreshed with water, but it must not be repeated too often, nor given in large quantities, for too much moisture will cause them to rot. These will make good plants by the following autumn, when they may be transplanted into the borders of the pleasure-garden, where they will flower the following summer.

Some people who are covetous to have their plants flower, suffer the stalks to remain till the flowers are decayed, and then cut them off to plant; but by that time the stalks are grown hard, so but few of them

succeed, and those which do, will not be near so good plants as those which are planted earlier; therefore it will be better to sacrifice the flowers of some roots for this purpose. These plants delight in a soft, rich, loamy soil, not too moist or stiff, in which they will thrive and flower very strong, but they do not care for much dung, which very often causes the roots to canker and rot, so that in the rich dunged lands about London, they do not thrive well. As these plants grow tall, they should be planted in the middle of large borders, and not crowded with other plants, for their roots extend to a large distance; so if they are incommoded by other roots, it will stint their growth.

I have not seen any double flowers of the two other varieties, but have been informed that there are of both the white and the flesh-colour with double flowers in some of the French gardens. These make a variety, but are not so beautiful as the scarlet, so are not much esteemed.

The second sort is commonly called *Red German Catchfly*. This hath been found growing naturally upon the rocks in Edinburgh Park, and in some places in Wales. It was formerly cultivated in flower-gardens for ornament, but since this sort with double flowers hath been produced, the single has been almost banished out of the gardens. This hath long, narrow, Grass-like leaves, which come out from the root without order, sitting close to the ground; between these come up strait single stalks, which in good ground rise a foot and half high; at each joint of the stalk come out two leaves opposite, of the same form as the lower, but decrease in their size upward; under each pair of leaves, for an inch in length, there sweats out of the stalk a glutinous liquor, which is almost as clammy as birdlime, so that the flies which happen to light upon these places, are fastened to the stalk, where they die, from whence it had the title of *Catchfly*. The stalk is terminated by a cluster of purple flowers, and from the two upper joints come out on each side of the stalk a cluster of the same flowers, so that the whole form a sort of loose spike. These appear in the beginning of May, and the single flowers are succeeded by roundish seed-vessels, which are full of small angular seeds ripening in July.

It may be propagated in plenty by parting of the roots in autumn, at which time every slip will grow; or if the seeds are sown in the same manner as is directed for the first sort, the plants with single flowers may be raised in plenty. This delights in a light moist soil and a shady situation.

The double flowering of this sort was accidentally obtained from the seeds of the single. This hath not been known forty years in the English gardens, but it is now so common as to have excluded that with single flowers; it differs only from that in the doubleness of the flowers. As this never produces seeds, so it can only be propagated by parting and slipping of the roots; the best time for this is in autumn, at which time every slip will grow. If this is performed in September, the slips will have taken good root before the frost, and will flower well the following summer; but if they are expected to flower strong, the roots must not be divided into small slips, though for multiplying the plants, it matters not how small the slips are. These should be planted on a border exposed to the morning sun, and shaded when the sun is warm till they have taken root. If the slips are planted in the beginning of September, they will be rooted strong enough to plant in the borders of the flower-garden by the middle or latter end of October. The roots of this sort multiply so fast, as to make it necessary to transplant and part them every year; for when they are let remain longer, they are very apt to rot. This sort requires the same soil and situation as the former.

The third sort grows naturally by the side of ditches and in moist pastures in many parts of England, so is seldom admitted into gardens; it hath a perennial root, from which arise many branching diffused stalks from

LYC

from two to three feet high, garnished with oval acute-pointed leaves, placed by pairs at each joint, and are terminated by clusters of purple flowers, which appear in April and May. The male flowers grow upon separate plants from the female. The latter produces seeds which ripen in July; the stalks decay in autumn, but the roots continue several years.

There is a variety of this with double flowers, which is cultivated in gardens, by the title of Red Bachelor's Button. This is an ornamental plant, and continues long in flower. It is propagated by slips, which should be planted the beginning of August in a shady border of loamy earth, where they will take root in about six weeks or two months, and may then be transplanted into the borders of the flower-garden. These roots should be annually transplanted, otherwise they frequently rot; and young plants must be propagated by slips to supply the decay of the old roots, which are not of very long duration. This sort thrives best in a soft loamy soil, and in a shady situation, where they have only the morning sun.

The fourth sort is very common upon dry banks on the side of roads in most parts of England, so is not admitted into gardens; there is a variety of this with purple flowers, which I find is by some supposed to be the same as the third, but is very different, for the stalks of this are branched out much more; the leaves are longer and more veined, and the flowers of this stand singly upon pretty long foot-stalks, so are not produced in clusters like those of the third. This is also very hairy, and the empalement of the flowers is swollen like inflated bladders. This flowers near a month after the other, but the male and female flowers grow upon different plants, as in the former. There is a variety of this with double flowers, which is propagated in gardens by the title of Double white Bachelor's Button, and is an ornamental plant in the flower-garden; though being white it doth not make so good an appearance as the other, however it adds to the variety. This is propagated in the same way as the double sort before-mentioned, but the plants will thrive in a drier soil, and a more open exposure than that.

The fifth sort grows very common in moist meadows, and by the side of rivers in most parts of England, where it is intermixed with the Grass. This rises with upright unbranched stalks near a foot and a half high, garnished with narrow spear-shaped leaves, placed by pairs opposite at each joint. The stalks are slender, channelled, and are terminated by six or seven purple flowers upon pretty long foot-stalks, which branch out. The empalement of the flower is striped with purple, and the petals of the flowers are deeply jagged in four narrow segments, which appear as if torn; from whence the country people have given it the appellation of Ragged Robin. It flowers in May, and the seeds ripen in July. This sort is never kept in gardens; but there is a variety of it with very double flowers, which is propagated by the gardeners for ornament. It only differs from the single in the multiplicity of the petals, and produces no seeds, so is propagated by slips in the same manner as the second sort. It is commonly known by the title of Double Ragged Robin.

The sixth sort grows naturally on the Alps, in Lapland, and the other cold parts of Europe. This is a perennial plant which delights in a moist soil. The stalks of this are erect, half a foot high, garnished with narrow spear-shaped leaves placed by pairs opposite, like the former sort, but are a little shorter and broader; the bottom leaves are broader than those upon the stalks, and sit close to the ground; they are smooth, and of a deep green: the flowers are produced in a corymbus on the top of the stalk, sitting close together; they are of a purple colour, and the petals are cut in the middle. This flowers the beginning of June, and the seeds ripen in August. It is propagated by seeds, and also by parting of the roots; it must have a moist soil and a shady situation, otherwise the plants will not thrive. The time for trans-

LYC

planting the plants, and parting the roots, is the same as for the second sort, and the seeds may be sown upon a shady border in March. In dry weather the ground must be kept moist, otherwise the seeds will not grow. When the plants come up, and are fit to remove, they should be transplanted into a shady border, where they may remain to flower.

The seventh sort grows naturally in Siberia: this hath a perennial root, from which arise many narrow leaves sitting close to the ground. The stalks rise a foot high, dividing into branches by pairs. The flowers grow out from the division of the branches, as also at the top of the stalks. They are composed of five white petals, which are divided in the middle; these appear in June, and are succeeded by roundish capsules filled with small angular seeds, which ripen in August. This requires the same treatment as the former sort.

The eighth sort was brought from Portugal to England, and is probably a variety of one with single flowers, which grows naturally in that country, but is different from any we have in England. This approaches nearest to the Double Ragged Robin, but is different from that. It hath a perennial root, from which arise many oblong narrow leaves sitting close to the ground. It divides into separate heads like the second sort, and from each of these come out an upright stalk about nine inches high, which divides upwards by pairs, and from the middle of each division comes out a slender foot-stalk two inches long, sustaining one double purple flower at the top, whose petals are very much jagged at their points; the empalements of the flowers are marked with deep purple stripes. From the side of the stalks there are also foot-stalks come out at the wings, which for the most part sustain but one flower, though sometimes they have two; these flowers being very double, are never succeeded by seeds. The usual time of this plant flowering is in June, but sometimes it sends out fresh stalks, which have flowers in the autumn. It is propagated by slips in the same manner as the third and fourth sorts, but coming from a warm country, it is impatient of much cold, and requires a particular treatment, for it does not thrive well in pots; nor will it live through the winter in open borders, so that the only situation in which I have seen it thrive, was where it was planted as close as possible to a south wall in dry undunged earth; for in rich or moist ground the roots presently rot, as they also do when they are watered. If they are planted in brick rubbish, they will still do better. I was favoured with this plant by John Browning, Esq; of Lincoln's-inn, who received it from Portugal.

The ninth sort grows naturally in the northern parts of Europe. It is like the fourth sort, but the petals of the flowers do not extend beyond the empalement, and the empalements are much larger and more swollen.

The other SPECIES of LYCHNIS are now ranged under the following genera, viz.

AGROSTEMMA; CUCUBALUS, SAPONARIA, and SILENE, to which articles the reader is desired to turn for those which are not here enumerated.

LYCIUM. Lin. Gen. Plant. 232. Jasminoides. Nisfol. Act. R. Par. 1711. Rhamnus. C. B. P. 477. Boxthorn.

The CHARACTERS are,

The flower hath a small, obtuse, permanent empalement, which is erect, and divided into five parts at the top; the flower is funnel-shaped, of one petal, with an incurved tube, whose brim is cut into five obtuse segments, which spread open. It has five awl-shaped stamens, which are a little inclined and shorter than the tube, terminated by erect summits. In the center is situated a roundish germen supporting a single style, which is longer than the stamens, crowned by a thick bifid stigma; the germen afterwards becomes a roundish berry with two cells, inclosing kidney-shaped seeds fastened to the middle partition.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which

which includes those plants whose flowers have five stamina and one style.

The SPECIES are,

1. LYCIUM (*Afrum*) foliis lineari-longioribus, tubo florum longiori, segmentis obtusis. *Boxthorn with longer linear leaves, a longer tube to the flower, and obtuse segments.* Lycium foliis linearibus. Hort. Cliff. 57. *Boxthorn with linear leaves.*
2. LYCIUM (*Italicum*) foliis lineari-brevioribus, tubo florum breviori, segmentis ovalibus patentissimis. *Boxthorn with shorter linear leaves, a shorter tube to the flower, and oval segments spreading open.*
3. LYCIUM (*Salicifolium*) foliis cuneiformibus. Vir. Cliff. 14. *Boxthorn with wedge-shaped leaves.* Jasminoides aculeatum, falcis folio, flore parvo ex albo purpurascens. Mitchel. Gen. 224. *Prickly Bastard Jasmine with a Willow leaf, and a small purplish white flower.*
4. LYCIUM (*Barbarum*) foliis lanceolatis crassiusculis, calycibus trifidis. Lin. Sp. Plant. 192. *Boxthorn with spear-shaped thick leaves, and trifid empalements.* Jasminoides aculeatum, polygoni folio, floribus parvis albidis. Shaw. Afr. 349. f. 349. *Prickly Bastard Jasmine, with a Knot-grass leaf, and small whitish flowers.*
5. LYCIUM (*Chinense*) foliis ovato-lanceolatis, ramis diffusis, floribus solitariis patentibus alaribus, stylo longiori. *Boxthorn with oval spear-shaped leaves, diffused branches, and single spreading flowers proceeding from the sides of the branches, with a longer style.*
6. LYCIUM (*Halimifolium*) foliis lanceolatis acutis. *Boxthorn with spear-shaped acute leaves.* Jasminoides Sinense halimi folio longiore & angustiore. Du Ham. 306. *China Bastard Jasmine with a narrower and longer leaf.*
7. LYCIUM (*Capense*) foliis oblongo-ovatis, crassiusculis, confertis, spinis robustioribus. *Boxthorn with oblong, oval, thick leaves growing in clusters, and stronger spines.*
8. LYCIUM (*Angustifolium*) foliis lineari-lanceolatis confertis, calycibus brevibus acutis. *Boxthorn with linear spear-shaped leaves growing in clusters, and short acute empalements.*
9. LYCIUM (*Inermis*) inermis, foliis lanceolatis, alternis, perennantibus. *Smooth Boxthorn, with spear-shaped ever-green leaves placed alternate.*
10. LYCIUM (*Cordatum*) foliis cordato-ovatis, sessilibus, oppositis perennantibus, spinis crassis bigeminis, floribus confertis. *Lycium with oval heart-shaped leaves placed opposite, which are ever-green, and sit close to the stalks, with thick double spines, and flowers growing in clusters.* Arbor Africana spinosa, foliis crassis cordatis & conjugatis, spinis crassis bigeminis. Hern. Cat. 4. *Prickly African-tree with thick heart-shaped leaves growing by pairs, and thick double spines.*

The first sort grows naturally in Spain, Portugal, and at the Cape of Good Hope. This rises with irregular shrubby stalks ten or twelve feet high, sending out several crooked knotty branches, covered with a whitish bark, and armed with long sharp spines, upon which grow many clusters of narrow leaves; these thorns often put out one or two smaller on their sides, which have some clusters of smaller leaves upon them; the branches are garnished with very narrow leaves an inch and a half long, and at the base of these come out clusters of shorter and narrower leaves. The flowers come out from the side of the branches, standing upon short foot-stalks; they have a short permanent empalement of one leaf, which is tubulous, and cut into five segments at the brim; it is funnel-shaped, of one petal, with a long incurved tube, cut into five obtuse segments at the brim; they are of a dull purple colour, and have five stamina almost as long as the tube, with erect summits. In the center is situated a roundish germen, supporting a style which is longer than the stamina, crowned by a bifid stigma. The germen afterward turns to a roundish fleshy berry, of a yellowish colour when ripe, inclosing several hard seeds. This usually flowers in June and July, and the seeds ripen in the autumn; but there is frequently a few flowers come out in all the summer months.

It may be propagated either by seeds, cuttings, or

layers. If by seeds, they should be sown in the autumn soon after they are ripe; for if they are kept out of the ground till spring, they seldom come up the first year. If the seeds are sown in pots, the pots should be plunged into some old tan in the winter, and in very severe frost covered with Peas-haulm or straw, but in mild weather should be open to receive the wet; in the spring the pots should be plunged into a moderate hot-bed, which will soon bring up the plants; these must be inured to bear the open air as soon as the danger of frost is over, and when they are three inches high, they may be shaken out of the pots, and each planted in a small separate pot, filled with loamy earth, and placed in the shade till they have taken new root, when they may be removed to a sheltered situation, where they may remain till the autumn; then they should be either removed into the green-house, or placed under a hot-bed frame to shelter them from hard frost; for these plants are too tender to live in the open air in England, so they must be kept in pots and treated in the same way as Myrtles, and other hardy green-house plants; but when the plants are grown strong, there may be a few of them planted in the full ground in a warm situation, where they will live in moderate winters, but in hard frosts they are commonly destroyed. If the cuttings of these plants are planted in a shady border in July, and duly watered, they will take root, and may then be treated in the same way as the seedling plants.

The second sort was raised in the Chelsea garden from seeds which came from the Cape of Good Hope. This hath an irregular shrubby stalk like the former, but seldom rise more than four or five feet high; the large leaves are shorter and a little broader than those of the first, but the tufts of small leaves are narrower; the tube of the flower is shorter, the brim is deeper cut into oval segments which spread open; the empalement is shorter, and cut into acute segments; the flowers and fruit are also smaller. These differences are permanent, in all the plants which I have two or three times raised from seeds. It flowers about the same time as the first, and may be propagated in the same way; the plants also require the same culture.

The third sort grows naturally in the hedges in the south of France, in Spain and Italy. This hath many irregular shrubby stalks, which rise eight or nine feet high, sending out several irregular branches, covered with a white bark, and armed with pretty strong thorns; the leaves are narrow at bottom, growing broader upward, and are of a pale green colour. The flowers come out from the side of the branches; they are of a purplish white colour and small, so make no great appearance. This sort flowers in June and July, but rarely produces any seeds in this country. The leaves of this remain till winter, when they fall off.

It may be propagated by cuttings or layers, in the same manner as the first sort. The plants will live abroad in a sheltered warm situation, but in very hard frost they should be covered with straw or litter, otherwise the branches will be killed, and sometimes the roots are destroyed where they have not some cover.

The fourth sort was brought from Africa by the late Dr. Shaw, where it grows naturally. This hath a shrubby stalk which rises seven or eight feet high, sending out several irregular branches, which are armed with strong spines, and garnished with short, thick, spear-shaped, oval leaves, which stand without order. The flowers come out from the side of the branches; they are small and white, so make little appearance. This flowers in July and August, but does not produce seeds in England. It may be propagated by cuttings in the same way as the first sort, but is too tender to live in the open air in winter in this country, so the plants must be kept in pots, and removed into the green-house in autumn, and treated in the same way as other hardy kinds of green-house plants.

The

The fifth sort grows naturally in China, from whence the seeds were brought to England a few years past, and the plants were raised in several gardens, and by some were thought to be the Thea. This rises with weak, irregular, diffused branches to a great height, but require support, otherwise they will trail upon the ground: I have measured some of these branches, which in one year has been upward of twelve feet long: the lower leaves are more than four inches long, and three broad in the middle: they are of a light green and a thin consistence, placed without order on every side the branches; as the shoots advance in length, so the size of the leaves diminish, and toward the upper part they are not more than an inch long, and a quarter of an inch broad; they sit close to the stalks on every side. The flowers come out singly at every joint toward the upper part of the branches, standing upon short slender foot-stalks; they are of a pale colour, with short tubes; the brims are spread open broader than either of the former sorts, and the style is considerably longer than the tube of the flower. This sort flowers in August, September, and October; the plant is very hardy, and retains its leaves till November before they decay. It propagates fast enough by its creeping roots, which send out suckers at a great distance, and the cuttings thrust into the ground will take root as freely as Willows.

The sixth sort grows naturally in China, from whence the seeds were brought to the Royal Garden at Paris, and the seeds were sent me by Dr. Bernard de Jussieu, demonstrator of the plants in that garden. This rises with a shrubby stalk to the height of four or five feet, sending out many irregular branches, covered with a very white bark, and armed with a few short spines; the leaves are about three inches long, and one broad in the middle; they are placed alternately on the branches, and are of a pale green colour. The flowers of this sort appear in June and July, which are succeeded by small round berries that ripen in the autumn, when they are as red as coral. This sort is propagated by cuttings, which should be planted in the spring before they begin to shoot, in a border exposed to the morning sun, where they will take root very freely; but these should not be removed till the autumn, when they may be planted to cover walls, for the branches are too weak to support themselves; and as the leaves continue green as long as any of the deciduous plants, so they are proper plants for such purposes.

The seventh sort was raised in the Chelsea garden from seeds, which were brought me from the Cape of Good Hope. This rises with shrubby branching stalks seven or eight feet high, which are armed with long strong thorns, that have several clusters of leaves upon them; the branches are garnished with small, oblong, oval leaves, which are placed without order; sometimes they come out in small clusters from one point, at others they are single, standing on every side the stalk; these are of a light green, and a pretty thick consistence, continuing green all the year. These plants have not as yet flowered here, so I can give no account of them; but by the fruit which I received entire, I make no doubt of its belonging to this genus.

This sort is pretty hardy, for it has lived abroad four winters, where it was planted against a south-east wall. It may be propagated either by layers or cuttings, in the same manner as the first; and when the plants have obtained strength, they may be planted in a warm situation, where they will live with very little shelter in severe frost. The branches of this sort are stronger than those of the former, so will not require the same support. It will be proper to keep a plant of this in shelter to preserve the kind, lest those in the open air should be destroyed.

The eighth sort has much the appearance of the first, but the branches are not so strongly armed with thorns; they have also a whiter bark, the leaves are

broader and of a lighter green, standing in clusters at every joint. The flowers are smaller, of a deeper purple colour, and have much shorter empalements, which are cut into acute segments. It flowers at the same time with the first sort, but does not produce any seeds in this country; it is not so hardy as the former sort, so requires protection from very hard frost; therefore the plants should be kept in pots and housed in the winter, treating them in the same way as other hardy green-house plants. It may be propagated by cuttings or layers, in the same way as the first sort.

The ninth sort has been long an inhabitant of the Chelsea garden; it was raised from seeds which came from China, and was for many years taken for the Tea-tree, till it produced some flowers, which discovered its true genus. This rises with a strong woody stalk six or seven feet high, sending out many smooth branches, which are covered with a brown bark having no thorns; they are garnished with spear-shaped leaves about three inches long, and near three quarters of an inch broad, placed alternately on the branches, standing upon short foot-stalks; they are of a deep green, and continue all the year. The flowers are white, and of the same shape with the others of this genus, but there has not been any seeds of this sort as yet produced in England.

This plant will live in the open air, if it is planted in a warm situation and a dry soil; but it is of slow growth, seldom shooting more than three or four inches in a season; it is also difficult to propagate, for the branches which are laid down will not take root in less than two years, and the cuttings are with difficulty made to grow. The best time to plant them is in May, in pots filled with light loamy earth, plunging them into an old bed of tanners bark, covering the pots close with bell or hand-glasses, to exclude the external air; these should be shaded every day from the sun; these cuttings should be refreshed with water once a week, but it must not be given to them in too great plenty. Those cuttings which succeed, will have put out roots by the beginning of August, when they may be taken up and planted in small pots, placing them in the shade till they have taken new root; and then they may be placed with other hardy exotic plants in a sheltered situation, till the end of October, when they may be put under a common frame to shelter them in winter. When the plants have acquired strength, they may be shaken out of the pots, and planted in the full ground in a warm situation, where, if they are sheltered in severe frosts, they will thrive better than in pots.

The tenth sort grows naturally at the Cape of Good Hope, from whence the seeds were sent to Holland a few years past, where the plants were raised. This is a low shrubby plant, which sends out branches from the ground upward, which are covered with a dark green bark, and are armed with short strong thorns, which come out by pairs, and sometimes there are double pairs upon the same foot-stalk; these are situated just below the leaves, and where there are four, two of them point upward, and the other two downward. The leaves are heart-shaped, not much larger than those of the Box-tree, of the same consistence and colour, terminating in acute points; they are placed by pairs opposite, upon very short foot-stalks, standing pretty close together; these continue green all the year. The flowers come out from the side of the branches upon short slender foot-stalks, each supporting five or six small white flowers, which grow in a cluster at the top; these have very short empalements, and pretty long tubes, divided at the brim into five acute segments. These flowers have an agreeable odour; they appear in July and August, but are seldom succeeded by seeds in England.

This sort may be propagated by cuttings in the same manner as the first sort, which, if planted in July, and shaded from the sun, will take root very freely; then they should be planted into separate small pots, and placed in the shade till they have

taken new root, after which they may be treated in the same manner as the former sort. This plant has not as yet been planted in the full ground in England, but it lives through the winter under a common frame.

The other species which were included in this genus, are now removed to CELASTRUS.

LYCOPERSICON. Tourn. Inst. R. H. 150. tab. 63. Solanum. Lin. Gen. Plant. 224. [of *Aux*, a wolf, and *Perfica*, Lat. a Peach.] Love Apples, or Wolf's Peach.

The CHARACTERS are,

The flower has a permanent empalement of one leaf, which is cut into five acute segments at the top, and is permanent. The flower has one petal, which is wheel-shaped, with a very short tube, and a large five-cornered brim, which spreads open and is plaited. It hath five small awl-shaped stamina, terminated by oblong summits which close together. It hath a roundish germen, supporting a slender style the length of the stamina, crowned by an obtuse stigma. The germen afterward becomes a roundish fleshy fruit or berry, divided into several cells, inclosing many flat seeds.

This genus of plants is ranged in the seventh section of Tournefort's second class, which includes the herbs with a wheel-shaped flower of one leaf, whose pointal becomes a soft fruit. Dr. Linnaeus has joined this genus, and also the Melongena of Tournefort, to the Solanum, which he places in the first section of his fifth class, which includes those plants whose flowers have five stamina and one style; but as there are numerous species of Solani, so it is much better to keep these separate, to avoid confusion, which if we allow the fruit as a characteristic note, should be done; for as the fruit of the Solanum has but two cells, and the fruit of this many, so that distinction may be allowed to separate the genera.

The SPECIES are,

1. **LYCOPERSICON** (*Galenii*) caule inermi herbaceo, foliis pinnatis incis, fructu rotundo glabro. *Love Apple with an herbaceous unarmed stalk, pinnated cut leaves, and a smooth round fruit. Lycopersicon Galeni. Ang. 217. The Wolf Peach of Galen.*
2. **LYCOPERSICON** (*Esculentum*) caule herbaceo hirsutissimo, foliis pinnatis, incis, fructu compresso sulcato. *Love Apple with a very hairy herbaceous stalk, winged cut leaves, and a compressed furrowed fruit. Solanum pomiferum, fructu rotundo striato molli. C. B. P. 167. Apple-bearing Nightshade, with a soft, round, striated fruit, commonly called Tomatas by the Spaniards.*
3. **LYCOPERSICON** (*Aethiopicum*) caule inermi herbaceo, erecto, foliis ovatis dentato angulatis, subspinosis fructu subrotundo sulcato. *Love Apple with an herbaceous, erect, unarmed stalk, oval angular leaves indented, having a few spines, with a roundish furrowed fruit. Lycopersicon fructu striato duro. Tourn. Inst. R. H. 150. Wolf's Peach with a hard striated fruit.*
4. **LYCOPERSICON** (*Pimpinellifolium*) caule inermi herbaceo, foliis inæqualiter pinnatis, foliolis obtuse-dentatis, racemis simplicibus. *Love Apple with an herbaceous unarmed stalk, leaves unequally winged, whose lobes are bluntly indented, and simple branches of flowers. Lycopersicon inodorum. Juss. Wolf's Peach having no scent.*
5. **LYCOPERSICON** (*Peruvianum*) caule inermi herbaceo, foliis pinnatis tomentosis incis, racemis bipartitis foliolis. *Love Apple with an unarmed herbaceous stalk, winged cut leaves, which are downy, and a leafy double spike of flowers. Lycopersicon pimpinellæ sanguisorbæ foliis. Feuill. Obf. 3. p. 37. Wolf's Peach with leaves like Burnet.*
6. **LYCOPERSICON** (*Procumbens*) caule herbaceo, procumbente, foliis pinnatifidis, glabris, floribus solitariis alaribus. *Love Apple with an herbaceous trailing stalk, wing-pointed smooth leaves, and flowers growing singly from the wings of the stalk.*
7. **LYCOPERSICON** (*Tuberosum*) caule inermi herbaceo, foliis pinnatis integerrimis. *Love Apple with an unarmed herbaceous stalk, and winged leaves which are entire. Solanum tuberosum esculentum. C. B. P. 167. Esculent*

tuberos Nightshade, commonly called Potatoe, by the Indians Batatas.

The first sort here mentioned is supposed to be the Lycopersicon of Galen. This is an annual plant, with an herbaceous, branching, hairy stalk, which will rise to the height of six or eight feet, if supported, otherwise the branches will fall to the ground: these are garnished with winged leaves of a very rank disagreeable odour, composed of four or five pair of lobes terminated by an odd one; these are cut on their edges, and end in acute points. The flowers come out from the side of the branches upon pretty long foot-stalks, each sustaining several yellow flowers, ranged in a single long bunch or thyrse, and are succeeded by round, smooth, pulpy fruit, about the size of a large Cherry. There are two varieties of this, one with yellow, and the other with red fruit. The plants flower from June till the frost stops them, and the fruit ripens in succession from the end of July, till the frost kills the plants; this sort is used in medicine. The second sort is very like the first, excepting the fruit, which differ greatly; for those of the second sort are very large, compressed at both ends, and deeply furrowed all over the sides. This sort never varies to the other, so that it is undoubtedly a distinct species. This is the sort which is commonly cultivated to put into soups; and the Portuguese, Spaniards, and some others, use them in many of their sauces, to which they give an agreeable acid flavour. The third sort is also annual; this rises with an erect herbaceous stalk a foot and a half high, dividing into several branches, garnished with oval angular leaves, from three to four inches long, and almost three inches broad in the middle; they are placed alternately upon pretty long foot-stalks, which have one or two short spines upon them, as there also is upon the midrib of the leaves. The flowers come out singly upon foot-stalks from the side of the branches; they are white, and are succeeded by red striated fruit, which are firmer than those of the other sorts, and about the size of Cherries. This fruit ripens in the autumn, and the plants decay soon after.

The fourth sort is somewhat like the first, but the leaves are unequally winged, having some smaller lobes placed between the large ones; the lobes of this are shorter, broader, and not cut like those of the first, but have some obtuse indentures toward their base. The leaves of this sort have not that rank disagreeable odour which the two first have; the fruit of it is not so large as those of the first, but they are round and smooth, and are very late before they ripen here; so that unless the plants are raised early in the spring, they will not produce ripe fruit.

The fifth sort is also annual; this hath a very branching herbaceous stalk, spreading out into many divisions, and is not so hairy as the two first; the leaves are composed of a greater number of lobes, which are much shorter and more indented on their edges, where they are a little waved, and are downy. The flowers stand upon very long foot-stalks, which branch out and support a large number of flowers at the top; these have a longer style than those of the other species, which is permanent, remaining on the top of the fruit. This sort is late in ripening the fruit, so that unless the plants are raised early in the spring, the fruit will not ripen in England.

The seeds of these two sorts were sent from Peru by Mr. Joseph de Jussieu to the Royal Garden at Paris, part of which was sent me by his brother Dr. Bernard de Jussieu, of the Royal Academy of Sciences. The sixth sort was raised by Mr. James Gordon, gardener at Mile-end, who gave me some of the seeds, but from what country it came I could not learn. This hath very weak, trailing, smooth stalks, not more than a foot long, garnished with smooth leaves, standing by pairs opposite; these are regularly cut on the sides almost to the midrib, in form of a winged leaf; and these segments are also indented on their edges, and at their points. The flowers come

out

out on the side of the stalks singly; they are of a whitish yellow colour, and have a pretty large spreading empalement, which is deeply cut at the brim into many acute segments which spread open. The flowers are succeeded by small roundish berries a little compressed at the top, of an herbaceous yellow colour when ripe.

These plants are all propagated by sowing their seeds on a moderate hot-bed in March, and when the plants are come up two inches high, they should be transplanted into another moderate hot-bed, at about four inches distance from each other, observing to shade them until they have taken root; after which they must have frequent waterings, and a large share of fresh air; for if they are too much drawn while young, they seldom do well afterwards.

In May these plants should be transplanted either into pots filled with rich light earth, or into borders near walls, pales, or Reed-hedges, to which their branches may be fastened to support them from trailing on the ground, which they otherwise will do, and then the fruit will not ripen; so that where these plants are cultivated for the sake of their fruit, they should be planted to a warm aspect, and the branches regularly fastened as they extend, that the fruit may have the advantage of the sun's warmth to forward them, otherwise it will be late in the season before they are ripe, and they are unfit for use before; but when the plants are brought forward in the spring, and thus regularly trained to the south sun, the fruit will ripen by the latter end of July, and there will be a succession of it till the frost kills the plants.

Some persons cultivate these plants for ornament, but their leaves emit so strong offensive an odour on being touched, which renders them very improper for the pleasure-garden, and their branches extend so wide and irregular, as to render them very unsightly in such places; for as their branches cannot be kept within bounds, especially when they are planted in good ground, so they will appear very unsightly in such places; therefore the borders in the kitchen-garden, where these plants are placed for their fruit, must not be too rich, for in a moderate soil they will not be so luxuriant and more fruitful.

The Italians and Spaniards eat these Apples, as we do Cucumbers, with pepper, oil, and salt; and some eat them stewed in sauces, &c. and in soups they are now much used in England, especially the second sort, which is preferred to all the other. This fruit gives an agreeable acid to the soup, though there are some persons who think them not wholesome, from their great moisture and coldness, and that the nourishment they afford must be bad.

The third sort is never used either in the kitchen or for medicine, but the plants are preserved for the sake of variety, especially by those persons who are lovers of botany. This sort is propagated by seeds, which should be sown upon a hot-bed in the spring, and the plants afterward treated in the same manner as hath been directed for the Capsicum, with which this plant will thrive and produce plenty of fruit annually.

The seventh sort is the common Potatoe, which is a plant so well known now, as to need no description. Of this there are two varieties, one with a red and the other with a white root; that whose roots are red, have purplish flowers, but the white root has white flowers; these are supposed to be only accidental variations, and not distinct species.

The common name of Potatoe, seem to be only a corruption of the Indian name Batatas. This plant has been much propagated in England within thirty or forty years past, for although it was introduced from America about the year 1623, yet it was but little cultivated in England till of late; these roots being despised by the rich, and deemed only proper food for the meaner sort of persons; however, they are now generally esteemed by most people, and the quantity of them which are cultivated near

London, I believe, exceeds that of any other part of Europe.

This plant was always ranged in the genus of Solanum, or Nightshade, and is now brought under that title again by Dr. Linnæus; but as Lycopersicon has been established as a distinct genus, on account of the fruit being divided into several cells, by intermediate partitions; and as the fruit of this plant exactly agrees with the characters of the other species of this genus, I have inserted it here.

This is generally propagated by its roots, which multiply greatly if planted in a proper soil. The common way is, either to plant the small roots or offsets entire, or to cut the larger roots into pieces, preserving a bud or eye to each; but neither of these methods is what I would recommend, for when the smaller offsets are planted, they generally produce a greater number of roots, but these are always small; and the cuttings of the larger roots are apt to rot, especially if wet weather happens soon after they are planted; therefore what I would recommend is, to make choice of the fairest roots for this purpose, and to allow them a larger space of ground, both between the rows, as also in the rows, plant from plant; by which method I have observed, the roots have been in general large the following autumn.

The soil in which this plant thrives best, is a light sandy loam, not too dry or over moist; this ground should be well ploughed two or three times, in order to break and divide the parts; and the deeper it is ploughed, the better the roots will thrive. In the spring, just before the last ploughing, there should be a good quantity of rotten dung spread on the ground, which should be ploughed into the ground the beginning of March, if the season proves mild, otherwise it had better be deferred till the middle or latter end of that month; for if it should prove hard frost after the roots are planted, they may be greatly injured, if not destroyed thereby: but the sooner they are planted in the spring, after the danger of frost is over, the better it will be, especially in dry land. In the last ploughing, the ground should be laid even, and then the furrows should be drawn at three feet distance from each other, about seven or eight inches deep. In the bottom of this furrow the roots, should be laid at about one foot and a half asunder; then the furrow should be filled with the earth which came out, and the same continued through the whole field or parcel of land, intended to be planted.

After all is finished, the land may remain in the same state till near the time when the shoots are expected to appear above ground, when the ground should be well harrowed over both ways, which will break the clods, and make the surface very smooth; and by doing of it so late, it will destroy the young weeds, which, by this time, will begin to make their appearance; and this will save the expence of the first hoeing, and will also stir the upper surface of the ground, which, if much wet has fallen after the planting, is often bound into a hard crust, and will retard the appearance of the shoots.

As I have allotted the rows of Potatoes at three feet distance, it was in order to introduce the hoe-plough between them, which will greatly improve these roots; for by twice stirring and breaking the ground between these plants, it will not only destroy the weeds, but also loosen the ground, whereby every shower of rain will penetrate to the roots, and greatly improve their growth; but these operations should be performed early in the season, before the stems or branches of the plants begin to fall and trail upon the ground, because after that, it will be impossible to do it without injuring the shoots.

If these ploughings are carefully performed between the rows, and the ground between the plants in the rows hand-hoed, it will prevent the growth of weeds, till the haulm of the plants cover the ground; so that afterward there will be little danger of weeds growing

LYC

so as to injure the crop; but as the plough can only go between the rows, it will be necessary to make use of a hoe to stir the ground, and destroy the weeds in the rows; and if this is carefully performed in dry weather, after the two ploughings, it will be sufficient to keep the ground clean until the Potatoes are fit to take up.

In places where dung is scarce, many persons scatter it only in the furrows, where the roots are planted; but this is a very poor method, because when the Potatoes begin to push out their roots, they are soon extended beyond the width of these furrows, and the new roots are commonly formed at a distance from the old; so will be out of the reach of this dung, and consequently will receive little benefit from it. And as most of the farmers covet to have a crop of Wheat after the Potatoes are taken off the ground, so the land will not be so thoroughly dressed in every part, nor so proper for this crop, as when the dung is equally spread, and ploughed in all over the land, nor will the crop of Potatoes be so good. I have always observed, where this method of planting the Potatoes has been practised, the land has produced a fine crop of Wheat afterward, and there has scarce one shoot of the Potatoe appeared among the Wheat the following season, which I attribute to the farmers planting only the largest roots; for when they have forked them out of the ground the following autumn, there have been six, eight, or ten large roots produced from each, and often many more, and scarce any very small roots among them; whereas, in such places where the small roots have been planted, there has been a vast number of very small roots produced; many of which were so small as not to be discovered when the roots were taken up, so have grown the following season, and have greatly injured whatever crop was on the ground.

The haulm of these Potatoes is generally killed by the first frost in the autumn, when the roots should be taken up soon after, and may be laid up in sand in any sheltered place, where they may be kept dry, and secure from frost. Indeed the people who cultivate these roots near London, do not wait for the decaying of the haulm, but begin to take up part of them as soon as their roots are grown to a proper size for the market, and so keep taking up from time to time, as they have vent for them. There are others likewise, who do not take them up so soon as the haulm decays, but let them remain much longer in the ground; in which there is no hurt done, provided they are taken up before hard frost sets in, which would destroy them, unless where the ground is wanted for other crops; in which case, the sooner they are taken up the better, after the haulm is decayed. When these roots are laid up, they should have a good quantity of sand or dry earth laid between them, to prevent their heating; nor should they be laid in too large heaps, for the same reason. The kitchen-gardeners and farmers who live in the neighbourhood of Manchester, cultivate great quantities of this root, as the inhabitants of that populous town consume abundance of them, and are much fonder of them than of any other esculent plants; which has occasioned an emulation among the cultivators, of endeavouring to outvie each other, in getting the roots of a proper size for the table early in the season: in order to obtain this, they have made choice of those roots which produced the first flowers, and have left them to ripen their seeds, which they have sowed with great care; and the plants so raised, have generally been forwarder than the other; and by frequently repeating of this, they have so much improved the forwarding of the roots, as to have them fit for use in two months after planting; so that great improvements may be made by this practice, of many esculent plants, by persons who are curious and careful in trying the experiments.

LYCOPUS [*Λυκόπους*, of *λύκος*, a wolf, and *πῦς*, a foot; q. d. Wolf's-foot; because the ancients fancied, that the leaves of this plant resembled the

LYS

foot of a wolf,] it is commonly called Water Horehound.

This plant grows in great plenty on moist soils by the sides of ditches and ponds in most parts of England, but is never cultivated in gardens, so that it would be needless to say any thing more of it in this place.

LYSIMACHIA. Tourn. Inst. R. H. 141. tab. 59. Lin. Gen. Plant. 188. [this plant was so called of Lyfimachus, the son of a king of Sicily, who is said to have first found the virtues of it.] Loostrife; in French, *Corneille*.

The CHARACTERS are,

The empalement of the flower is permanent, and is cut into five acute segments, which are erect. The flower is of one petal, cut into five oblong oval segments to the bottom, which spread open. It hath five awl-shaped stamina about half the length of the petal, terminated by acute-pointed summits. In the center is situated a roundish germen, supporting a slender style the length of the stamina, crowned by an obtuse stigma. The germen afterward turns to a globular capsule with one cell, opening with ten valves, and filled with small angular seeds.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which includes the plants whose flowers have five stamina and one style.

The SPECIES are,

1. **LYSIMACHIA** (*Vulgaris*) *paniculata*, racemis terminalibus. Lin. Sp. Plant. 209. *Paniculated Loostrife*, with bunches of flowers terminating the stalks. *Lyfimachia lutea*, major, quæ *Dioscoridis*. C. B. P. 245. *Greater yellow Loostrife of Dioscorides*.
2. **LYSIMACHIA** (*Thyrsoflora*) racemis lateralibus pedunculatis. Lin. Sp. Plant. 147. *Loostrife with lateral spikes of flowers growing upon foot-stalks*. *Lyfimachia bifolia* flore globoso, luteo. C. B. P. 242. *Two-leaved Loostrife with a yellow globular flower*.
3. **LYSIMACHIA** (*Atropurpurea*) spicis terminalibus petalis, lanceolatis, staminibus corolla longioribus. Lin. Sp. Plant. 147. *Loostrife with spear-shaped spreading spikes of flowers terminating the branches, and stamina longer than the petals*. *Lyfimachia Orientalis* angustifolia flore purpureo. Tourn. Cor. 7. *Narrow-leaved Eastern Loostrife with a purple flower*.
4. **LYSIMACHIA** (*Ephemcrum*) racemis simplicibus terminalibus, petalis obtusis, staminibus corollâ brevioribus. Lin. Sp. Plant. 146. *Loostrife with spikes of flowers terminating the stalks, obtuse petals to the flower, and stamina shorter than the petal*. *Lyfimachia Orientalis* minor, foliis glaucis, annuentibus, flore purpureo. Hort. Piss. *Smaller Eastern Loostrife, with nodding grayish leaves and a purple spike of flowers*.
5. **LYSIMACHIA** (*Ciliata*) petiolis ciliatis, floribus cernuis. Lin. Sp. Plant. 147. *Loostrife with hairy foot-stalks and nodding flowers*. *Lyfimachia Canadensis* Jalappæ foliis. Sarr. Canad. *Canada Loostrife with a Jalap leaf*.
6. **LYSIMACHIA** (*Salicifolia*) spicâ simplici erecto terminali, petalis ovatis, staminibus corollâ longioribus. *Loostrife with a single erect spike terminating the stalk, oval petals, and stamina longer than the flower*. *Lyfimachia spicata*, flore albo, salicis folio. Tourn. Inst. R. H. 141. *Loostrife with a spike of white flowers and a Willow leaf*.
7. **LYSIMACHIA** (*Nummularia*) foliis subcordatis, floribus solitariis, caule repente. Vir. Cliff. 13. *Loostrife with leaves nearly heart-shaped, flowers growing singly, and a creeping stalk*. *Nummularia lutea* major. C. B. P. 309. *Greater yellow Moneywort*.
8. **LYSIMACHIA** (*Tenella*) foliis ovatis acutiusculis, pedunculis folio longioribus, caule repente. Lin. Sp. Plant. 148. *Loostrife with oval acute-pointed leaves, foot-stalks longer than the leaf, and a creeping stalk*. *Nummularia* minor, purpurascens flore. C. B. P. 310. *Smaller Moneywort with a purplish flower*.
9. **LYSIMACHIA** (*Nemorum*) foliis ovatis acutis, floribus solitariis, caule procumbente. Hort. Cliff. 52. *Loostrife with oval acute-pointed leaves, flowers growing singly, and a trailing stalk*. *Anagallis lutea* nemorum. C. B. P. 252. *Yellow Pimpernel of the woods*.

10. **LY-**

10. *LYSIMACHIA (Quadrifolia)* foliis subquaternis, pedunculis verticillatis unifloris. Lin. Sp. Plant. 147. *Looftrife with leaves generally placed by fours, and foot-stalks placed in whorls round the stalks, each sustaining a single flower.* *Lysimachia lutea minor, foliis nigris punctatis notatis. C. B. P. 245. Smaller yellow Looftrife with leaves marked with black spots.*

The first sort grows by the side of ditches and rivers in many parts of England, so is not often admitted into gardens, because the roots creep far in the ground, and send up stalks at a great distance, whereby it becomes often a troublesome plant; otherwise for the variety of its flowers, it might deserve a place in large gardens, especially in moist places, where better things will not thrive. It rises with upright stalks from two to three feet high, garnished with smooth spear-shaped leaves placed sometimes by pairs opposite; at others there are three, and frequently four of these leaves placed round the stalk at each joint. The upper part of the stalk divides into several foot-stalks, which sustain yellow flowers growing in a panicle; these have one petal which is deeply cut into five segments, spreading open. They appear in June and July, and are succeeded by roundish seed-vessels, filled with small seeds which ripen in the autumn. This is placed in the list of medicinal plants, but is not often used. If the roots of this plant are taken up from the places where it grows naturally in the autumn, and planted in a moist soil, they will thrive fast enough without care.

The second sort grows naturally in the northern parts of England; this hath a perennial creeping root, which sends up several erect stalks near a foot and a half high, garnished at every joint by two pretty long narrow leaves placed opposite, whose base sits close to the stalk; they are about three inches long, and more than half an inch broad toward their base, lessening gradually to the end, which terminates in acute points; the foot-stalks of the flowers come out opposite on each side of the stalks; they are an inch long, sustaining at their top a globular or oval thyrse of yellow flowers, whose stamina are much longer than the petals. This flowers at the same time with the former sort, but seldom produces seeds, for the roots creep so much as to render it barren. It is but seldom kept in gardens, for the same reason as the former is rejected; but those who are desirous to have it, may procure the roots and plant them in a moist soil, where it will soon spread.

The third sort is a biennial plant, which was discovered by Dr. Tournefort in the Levant, from whence he sent the seeds to the Royal Garden at Paris, where they succeeded, and many of the European gardens have from thence been furnished with it. This rises with an upright stalk about a foot high, garnished with spear-shaped leaves ending in acute points; these are placed by pairs opposite; they are smooth, and of a lucid green. The flowers grow in a loose spike, terminating the stalks; the flowers stand horizontally, spreading out on each side the stalk; they have longer tubes than the other species, and are of a purple colour. These appear in June, and the seeds ripen in September, soon after which the plants decay.

It is propagated by seeds, which should be sown on a moderate hot-bed in the spring, often watering the ground to bring up the plants; and if the season should prove warm, the glasses of the hot-bed should be shaded in the heat of the day; when the plants are up, they should have a large share of fresh air admitted to them in warm weather, to prevent their drawing up weak, and should be frequently refreshed with water. When they are fit to remove, they should be each planted in a separate pot, plunging them into a moderate hot-bed to forward their taking new root: after which they should be gradually inured to bear the open air, into which they should be removed by the beginning of June, where they may remain till October, when they should be removed into a common frame, where they may be sheltered from frost in winter, but should always enjoy the free air in mild

weather. The spring following some of the plants should be shaken out of the pots, and planted in borders; but a few of them should be put into larger pots, where they may flower and seed: this is called *Ephemerum* by Linnæus, but is not so.

When the plants come up, they must have plenty of air admitted to them in warm weather, to prevent their drawing up weak; then they may be planted into the borders of the pleasure-garden, where they will flower and produce ripe seeds the following summer.

The fourth sort is an annual plant, which is too tender to rise in the open air in this country, therefore the seeds should be sown on a moderate hot-bed in the spring, and the plants afterward treated in the same manner as hath been directed for the third sort.

The fifth sort was first brought from Canada, where it grows naturally; this hath a perennial creeping root, sending up many erect stalks about two feet high, garnished with oblong, oblique, smooth leaves, placed opposite; they are veined on their under side, and end in acute points. The flowers are produced from the wings of the stalks, each sitting upon a long slender foot-stalk; there are three or four of these arising from the short branches, which come out on each side the stalk, at all the upper joints. The flowers are like those of the first sort, but smaller, and hang downward; these appear in June and July, but are seldom succeeded by any seeds in England.

This sort spreads and propagates by roots, in as great plenty as the first, and is equally hardy, so requires no other culture.

The sixth sort grows naturally in Spain, and was formerly titled by John Bauhin and others, *Ephemerum*; this hath a perennial root, from which arise several upright stalks upward of three feet high, garnished with narrow, smooth, spear-shaped leaves, which stand opposite, and at the base of these come out short side branches, garnished with smaller leaves of the same shape. The flowers are produced in a long, close, upright spike, at the top of the stalk; they are cut into five oval segments, which are white, spreading open, and the stamina stand out longer than the petal. It flowers in June, and the seeds ripen in autumn.

This is the finest species of this genus, and as the roots of it do not spread like those of the other, so deserves a place in the pleasure-garden, where it is a very ornamental plant for shady borders. It loves a moist soil and a shady situation, where it will continue long in beauty. It may be propagated by parting the roots in autumn, but by this method it increases slowly; so that the only way to have it in plenty, is by sowing the seeds: these should be sown upon an east-aspected border in autumn, soon after they are ripe, then the plants will come up the following spring; but those which are sown in the spring will not grow the same year. When the plants come up they should be kept clean from weeds, and if they are too close, some of them may be drawn out and transplanted on a shady border, which will give the remaining plants room to grow till autumn, when they may be transplanted into the borders of the flower-garden where they are designed to flower; after which they will require no other culture but to keep them clean from weeds, and dig the ground between them every spring.

The seventh sort is commonly called Moneywort, or Herb Two-pence; this is a perennial plant, which grows naturally in moist shady places in most parts of England, so is not cultivated in gardens. The stalks of this trail upon the ground, and put out roots, by which it soon spreads to a great distance. The leaves are almost heart-shaped, and placed by pairs. The flowers come out singly from the side of the stalks; they are yellow, appearing in June and July.

The eighth sort is a small trailing plant, which grows upon bogs in mossy places in most parts of England, but cannot be cultivated on dry ground. The stalks seldom are more than three or four inches long, and

LYT

are terminated by three or four small flowers, of a bright purple colour, growing in a bunch. This flowers in June, but is rarely planted in gardens. The ninth sort is a perennial plant with trailing stalks, which grow naturally in moist woods in most parts of England, so is not cultivated in gardens. The leaves stand opposite at each joint; they are smooth, oval, and acute-pointed. The flowers come out singly from the side of the stalk, upon long foot-stalks; they are yellow, and spread open like the flowers of Chickweed. This flowers in May and June, and the seeds ripen in autumn.

The tenth sort grows naturally among Rushes and Reeds, by the rivers sides in Holland; this hath a perennial creeping root like the first. The stalks rise a foot high; they are slender, and are garnished by spear-shaped leaves an inch and a half long, and a quarter of an inch broad in the middle, placed sometimes by pairs, at others by threes, and often four at each joint, surrounding the stalk. The flowers also come out at each joint, four of them standing round the stalk in whorls, each having a distinct slender foot-stalk an inch long. The flowers are small and yellow; they appear in June, and are sometimes succeeded by seeds which ripen in autumn; it may be treated in the same manner as the first sort, and is equally hardy.

LYSIMACHIA GALERICULATA. See SCUTELLARIA.

LYSIMACHIA NON PAPPOSA. See OENOTHERA.

LYSIMACHIA SILIQUOSA. See EPILOBIUM.

LYTHRUM. Lin. Gen. Plant. 532. Salicaria. Tourn. Inst. R. H. 253. tab. 129. *Willow Herb, or purple Loosstrife.*

The CHARACTERS are,

The flower hath a cylindrical striated empalement of one leaf, indented at the brim in twelve parts, which are alternately smaller. It has six oblong blunt petals which spread open, whose tails are inserted in the indentures of the empalement, and ten slender stamina the length of the empalement, the upper being shorter than the lower, terminated by single rising summits. In the center is situated an oblong germen, supporting an awl-shaped declining style, crowned by a rising orbicular stigma. The germen afterwards turns to an oblong acute capsule with two cells, filled with small seeds.

This genus of plants is ranged in the first section of Linnaeus's eleventh class, intitled Dodecandria Monogynia, which includes those plants whose flowers have twelve stamina and one style.

The SPECIES are,

1. **LYTHRUM** (*Salicaria*) foliis oppositis cordato-lanceolatis, floribus spicatis dodecandris. Lin. Sp. Plant. 446. *Lythrum with heart spear-shaped leaves placed opposite, and flowers growing in spikes, having twelve stamina.* Salicaria vulgaris, purpurea, foliis oblongis. Tourn. Inst. R. H. 253. *Common purple Willow Herb with oblong leaves.*
2. **LYTHRUM** (*Tomentosum*) foliis cordato-ovatis, floribus verticillato-spicatis tomentosis. *Lythrum with oval heart-shaped leaves, and flowers growing in whorlly spikes, which are woolly.* Salicaria purpurea, foliis subrotundis. Tourn. Inst. R. H. 253. *Purple Willow Herb with roundish leaves.*

Houst. MSS. *American Willow Herb with a broader Hyssop leaf, and very small flowers.*

The first sort grows naturally by the side of rivers and ditches in most parts of England. It has a perennial root, from which come forth several upright angular stalks, which rise from three to four feet high; they are of a purple colour, and are garnished with oblong leaves, placed sometimes by pairs opposite, at others there are three leaves at each joint, standing round the stalk. The flowers are produced in a long spike at the top of the stalk; they are of a fine purple colour, and make a fine appearance. This flowers in July, and the seeds ripen in autumn: although this plant is despised, because it grows common, yet it merits a place in gardens better than many other which are propagated with care, because they are more rare. It is easily cultivated by parting the roots in autumn, and should be planted in a moist soil, where it will thrive and flower without any other care than the keeping it clean from weeds.

There is a variety of this with an hexangular stalk, and generally with three leaves at each joint; but this is only accidental, for the roots of this, when removed into a garden, come to the common sort.

The second sort hath perennial roots like the first, from which come out upright branching stalks three feet high, garnished with oval heart-shaped leaves about one inch long, and three quarters of an inch broad; they are downy, and placed by threes round the stalk. The flowers are produced in long spikes at the top of the stalks, but they are disposed in thick whorls, with spaces between each; they are of a fine purple colour, and appear at the same time with the former. This may be propagated in the same way as the first sort, and is equally hardy.

The third sort grows naturally in moist bogs in many parts of England, so is seldom admitted into gardens; this hath a perennial root, sending up two or three branching stalks about a foot high, garnished with narrow leaves, placed alternate. The upper part of the stalk is garnished with flowers, which come out from the side singly at each joint, standing close to the base of the leaves; they are small, and of a light purple colour, appearing in June, and the seeds ripen in autumn.

The fourth sort grows naturally in Spain and Portugal, in moist places by the side of waters; this has a perennial root and stalks like the first, which seldom grow more than one foot high, garnished with narrower and shorter leaves than the first, which are smooth, and placed by threes round the stalk. The flowers grow in spikes at the top of the stalks; they are of a light purple colour, and appear in July. The seeds ripen in autumn. This sort is hardy, and may be propagated in the same way as the first.

The fifth sort grows naturally in Spain and Portugal, from both which countries I have received the seeds.

The

L Y T

The root of this is perennial. The stalks are slender, not more than nine or ten inches long, spreading out on every side. The lower part of the stalks are garnished with oblong oval leaves, placed opposite. On the upper part of the stalks the leaves are narrower, and placed alternate. The flowers come out singly from the side of the stalks at each joint; they are larger than those of the common sort, and of a deeper purple colour, so make a fine appearance in July, when they are in beauty.

This sort has never produced any seeds in England, and the severe frost in 1740, killed all the plants here, since which time I have not seen any of them in the English gardens.

The sixth sort grows naturally in the northern parts of America; this rises with a stiff branching stalk a foot and a half high, garnished with oblong leaves, which are downy, and placed opposite, standing upon very short foot-stalks. The flowers are produced in whorls round the stalks; they are of a pale purple colour, and appear in July; these are succeeded by capsules with two cells, filled with seeds which ripen in autumn.

The seventh sort grows naturally in Virginia, from whence I received the seeds; this rises with an upright woolly stalk near two feet high, garnished with linear leaves placed opposite, upon short foot-stalks. The flowers come out from the wings of the stalks singly; they are small, tubulous, and of a pale purple colour, so make no great appearance; these appear in July, and in warm seasons only will perfect seeds; but the roots of this sort will increase so fast, as to render the propagating the plants by seeds unnecessary, when once obtained.

The eighth sort grows naturally in North America. It has a perennial root. The stalks are slender, about

L Y T

a foot high, garnished with linear leaves placed opposite, which are entire. The flowers come out singly from the wings of the leaves, on the upper part of the stalks; they are small, white, and have six petals. The empalement is streaked, and cut at the top into six parts, and the flower has six stamina. This flowers in June, and the seeds ripen in autumn.

The ninth sort was discovered by the late Dr. Houstoun at La Vera Cruz, growing in swamps, where the water had stagnated. This hath a ligneous root, from which arise two or three slender stalks upward of two feet high, garnished with oblong, oval, smooth leaves, which, on the lower part of the stalks are opposite, but those on the upper part are narrow and alternate. The flowers come out from the wings of the leaves, on the upper part of the stalk singly; they are small and white, having six petals and six stamina; these do not appear till the second year from seed, and have not produced any good seeds in England.

This sort is tender, so will not live in the open air in England. It is propagated by seeds, which should be sown in pots, and plunged into an old hot-bed the first season; for the seeds never rise the first year, unless they are sown in autumn; the pots should be sheltered in winter, and the spring following placed on a hot-bed to bring up the plants; these must be treated in the same way as other tender plants from the same country.

All the other sorts, when raised from seeds, should be sown in autumn, otherwise the seeds will remain a year in the ground, so that those seeds which are brought from America, never grow the same year they are sown; for which reason the ground should not be disturbed in which the seeds are sown, but left till the following spring, when the plants will come up if the seeds were good.

MACALEB. See CERASUS.
MADDER. See RUBIA TINCTORUM.
MMAGNOLIA. Plum. Nov. Gen. 38. tab. 7. Lin. Gen. Plant. 610. The Laurel-leaved Tulip-tree, vulgò.

The CHARACTERS are,

The empalement is composed of three oval concave leaves like petals, which soon fall away. The flower is composed of nine oblong blunt petals, which are concave. It hath a great number of short stamina which are compressed, and inserted into the germen, terminated by linear summits, adhering to every side of the stamina. It hath many oblong oval germina fastened to the receptacle, supporting recurved, contorted, short styles, with longitudinal hairy stigmas. The germen afterward become oval cones, with roundish compressed capsules almost imbricated, having one cell, opening with two valves, inclosing one kidney-shaped seed, hanging by a slender thread from the scale of the cone.

This genus of plants is ranged in the seventh section of Linnæus's thirteenth class, intitled Polyandria Polygynia, which includes those plants whose flowers have many stamina and styles. If Father Plumier's figure of the section of his fruit is exact, his must be a different genus from this; for the seeds of his are represented within the fruit, lying round a column.

The SPECIES are,

1. **MAGNOLIA** (*Glaucæ*) foliis ovato-lanceolatis subtus glaucis. Lin. Sp. 755. *Magnolia with oval spear-shaped leaves, which are gray on their under side.* *Magnolia*

M A G

lauri folio subtus albicante. Catesb. Hist. Car. 1. p. 39. Magnolia with a Bay leaf, which is whitish on the under side, commonly called Small Magnolia, or Laurel-leaved Tulip-tree.

2. **MAGNOLIA** (*Grandiflora*) foliis lanceolatis persistentibus, caule erecto arboreo. Fig. Plant. tab. 172. *Magnolia with spear-shaped leaves which are evergreen, and an erect tree-like stalk. Magnolia altissima, flore ingenti candido. Catesb. Carol. 2. p. 61. Tallest Magnolia, with a very large white flower, commonly called Greater Magnolia, or Tulip-tree, with a Laurel leaf.*
3. **MAGNOLIA** (*Tripetala*) foliis lanceolatis amplissimis annuis, petalis exterioribus dependentibus. *Magnolia with very large spear-shaped leaves which are annual, and the outer petals of the flower declining. Magnolia amplissima flore albo, fructu coccineo. Catesb. Car. 2. p. 80. Magnolia with a very large white flower and a scarlet fruit, commonly called Umbrella-tree.*
4. **MAGNOLIA** (*Acuminata*) foliis ovato-lanceolatis acuminatis annuis, petalis obtusis. *Magnolia with oval, spear-shaped, pointed leaves, which are annual, and obtuse petals to the flower. Magnolia flore albo, folio majore acuminato, haud albicante. Catesb. Car. 3. p. 5. Magnolia with a white flower, and a larger acute-pointed leaf, not whitish.*

The first sort grows pretty common in Virginia, Carolina, and in most other parts of North America, where it is found in moist places, near brooks; this usually grows about fifteen or sixteen feet high, with a slender stem. The wood is white and spongy,

the

the bark is smooth and white, the branches are garnished with thick smooth leaves, resembling those of the Bay, but are of an oval shape, and smooth on their edges, being white underneath. The flowers are produced in May and June at the extremity of the branches, which are white, composed of six petals which are concave, and have an agreeable sweet scent. After these are past, the fruit increases in size to be as large as a Walnut with its cover, but of a conical shape, having many cells round the outside, in each of which is lodged a flat seed, about the size of a Kidney-bean. This fruit is at first green, afterward red, and, when ripe, of a brown colour. The seeds, when ripe, are discharged from their cells, and hang by a slender thread.

In the natural places of its growth, there is a succession of the flowers on the trees for two months or more, during which time the woods are perfumed with them; but all those trees which have produced flowers in England, seldom have more than twelve or fourteen flowers upon each, which are of short duration, and are not succeeded by others; the leaves of this sort fall off in winter.

The young plants of this sort frequently retain their leaves through the greatest part of winter, and often do not fall off till the young shoots thrust them off, which has occasioned some persons to believe the plants were evergreen; but when they are three or four years old, they constantly cast their leaves by the beginning of November.

When these trees are transplanted from the places of their growth into dry ground, they make handsomer trees, and produce a greater number of flowers; this is to be understood of America, for in Europe they do not thrive so well in a dry soil as in a moist loamy land. The greatest number of these trees, which are now growing in England, are at his Grace the Duke of Norfolk's, at Workshop Manor, in Nottinghamshire. The second sort grows in Florida and South Carolina, where it rises to the height of eighty feet or more, with a strait trunk upward of two feet diameter, having a large regular head: the leaves of this tree resemble those of the common Laurel, but are much larger, and of a shining green on their upper side, and, in some trees, they are of a russet, or buff colour, on their under side; these leaves continue all the year, so that this is one of the most beautiful evergreen trees yet known. The flowers are produced at the end of the branches; they are composed of eight or ten petals, which are narrow at their base, but broad at their extremity, where they are rounded, and a little waved; these spread open wide, and are of a pure white colour. In the center is situated a great number of stamina and styles, fastened to one common receptaculum; these flowers are succeeded by oblong scaly cones in the places where it grows naturally, but the summers are not warm enough in England to produce any fruit to perfection, though some old plants do often form cones. These trees in their native places of growth begin to produce their flowers in May, and continue a long time in flower, so that the woods are perfumed with their odour the greatest part of summer; but those which have flowered in England, seldom begin till the middle or latter end of June, and do not continue long in beauty. The largest tree of this kind, which I have met with in England, is in the garden of Sir John Colliton, of Exmouth, in Devonshire, which has produced flowers for several years; there are also many pretty large plants of this sort in the gardens of his Grace the Duke of Richmond, at Goodwood, in Sussex, one of which has produced flowers several years; and in the nursery of Mr. Christopher Gray, near Fulham, there is one very handsome plant, which has also produced many flowers several years.

As this sort is a native of a warm country, it is a little impatient of cold, especially while young, therefore the plants should be kept in pots, and sheltered in winter for some years, until they have acquired strength, when they may be shaken out of the pots,

and planted in the full ground, but they must be planted in a warm situation, where they may be defended from the strong winds, and screened from the north and east, otherwise they will not live abroad.

There were a great number of young plants in England before the year 1739; but a great part of them were destroyed by that severe winter, and since then, there have been few good seeds sent to England, so that there are not many of the plants at present to be sold in the nurseries; and as almost every person who is curious in gardening, is desirous to have some of these beautiful trees in their gardens, the demand for them of late has greatly increased their value. If this tree can be so far naturalized as to endure the cold of our severest winters abroad, it will be one of the greatest ornaments to our gardens; and this we may hope, will, in time, be effected, by diligent observation and care; for the time when these plants suffer most, is in autumn, by the early frosts; for the extremity of the shoots being then tender, as they are then generally growing freely, a small frost will pinch them, and afterward the whole shoot frequently decays; so that the plants should be guarded against these early frosts, by covering their tops with mats until the shoots are hardened, after which time they will not be in so much danger of suffering; for I have constantly observed, that if these plants escape the early frosts of the autumn, they are seldom injured afterward: in the severe winter in the year 1739-40, I had a pretty large plant growing in the open air, which was killed down by the frost, and I supposed was entirely destroyed, as there was not the least appearance of life in the stem; so that after Midsummer I cut it down to the ground, but left the root remaining, which, to my great surprize, shot up again the year after. This I mention, to caution people from being too hasty in destroying plants after hard frost, but to have them wait until there can be no hopes of their recovery.

The third sort grows in Carolina pretty frequent, but in Virginia it is pretty rare; this usually grows from sixteen to twenty feet high, with a slender trunk; the wood is soft and spongy; the leaves of this tree are remarkably large, and are produced in horizontal circles, somewhat resembling an umbrella, from whence the inhabitants of those countries have given it the title of Umbrella-tree. The flowers are composed of ten or eleven white petals, which hang down without any order; the fruit is very like that of the former sort; the leaves of this sort drop off at the beginning of winter.

This tree is as yet very rare in Europe, but as it is propagated from seeds, we may hope to have it in greater plenty soon, if we can obtain good seeds from Carolina, for it is rarely met with in Virginia.

The fourth sort is also very rare in England; there are but few of the plants at present here, nor is it very common in any of the habitable parts of America: some of these trees have been discovered by Mr. John Bartram, growing on the north branch of Susquehannah river. The leaves of this tree are near eight inches long and five broad, ending in a point. The flowers come out early in the spring, which are composed of twelve white petals, shaped like those of the second sort; the fruit of this tree is longer than those of the other species, but in other respects agrees with them. The wood of this tree is of a fine grain, and an Orange colour.

All these sorts are propagated by seeds, which must be procured from the places of their natural growth; these should be put up in sand, and sent over to England as soon as possible; for if they are kept long out of the ground, they very rarely grow, therefore the seeds should be sown as soon as possible, when they arrive here.

Some years past I received a good quantity of these seeds from Carolina, which I sowed in pots as soon as I received them, and plunged the pots into an old hot bed of tanners bark; and with this management

I raised

M A G

I raised a great number of plants, but from the seeds which have been lately brought over, there have been but few plants produced; whether the seeds were not perfectly ripe when they were gathered, or from what other cause this has happened, I cannot say, but it is certain the fault must be in the seeds, because those before-mentioned were differently sown and managed by the several persons who received them, and the success was nearly alike every where.

There have been several plants of the first and second sort raised from layers, and some from cuttings; but these do not thrive so well as those which come from seeds, nor will they grow to near the size of those, so that it is much the best way to procure their seeds from America, and propagate them that way.

The first sort frequently comes up well from seeds, but the young plants are very difficult to keep the two first years; for if they are exposed much to the sun, their leaves change yellow and the plants decay; so the best way is to keep the pots plunged in a moderate hot-bed, and shade them every day from the sun with mats, giving them air in plenty when the weather is warm, and frequently refresh them with water; during the winter season they must be screened from frost, and in mild weather they must enjoy the free air, to prevent their growing mouldy, and they should have but little wet in winter. With this management the plants may be trained up, and when they have acquired strength, they may be planted in the open air, where they will thrive and flower, if they have a warm sheltered situation.

The second sort is not so difficult to train up as the first, but in order to get them forward, it will be proper when they are removed out of the seed-pots, to plant them each into a separate small pot, filled with soft loamy earth, and plunge them into a gentle hot-bed of tanners bark, observing to shade them from the sun, and admit proper air to them; but at Midsummer, if they are well rooted, they should be inured to the open air gradually, and then placed in a sheltered situation, where they may remain till autumn; but on the first approach of frost, they should be removed under shelter, otherwise the early frosts will pinch their tender shoots, which often occasions their dying downward after. When the plants have got strength, some of them may be turned out of the pots, and planted in the full ground in a warm sheltered situation, but part of them should be kept in pots, and sheltered in the winter, to preserve them, lest, by severe frost, the other should be killed.

If the plants make good progress, they will be strong enough to plant in the full ground in about six or seven years from seeds. The time for removing or shifting these plants is in March, before they begin to shoot, which may sometimes happen to be too soon to turn them out of the pots into the full ground, especially if the season proves late; but as there will be no danger in removing them out of the pots, the ball of earth being preserved to their roots, so it is best to defer this till the month of April; but it will be necessary to harden those plants which are intended to be planted out, by exposing them to the air as much as possible before, which will keep the plants backward, and prevent their shooting; for if they make shoots in the green-house, those will be too tender to bear the sun, until they are by degrees hardened to it, and the least frost will greatly pinch them, and such frosts frequently happen very late in the spring.

The two or three winters after these are planted out, it will be necessary to lay some mulch on the surface of the ground about their roots, as also to throw some mats over their heads, especially at the beginning of the morning frosts in autumn, for the reasons before given; but in doing this, the heads of the plant should never be too closely covered up, lest thereby the shoots should grow mouldy, for that will certainly kill the leading buds of every shoot, and prove to the full as injurious to them as the frost.

M A L

As the plants get strength, they will be better able to endure the cold of our climate, though it will be proper to lay some mulch about their roots every winter; and, in very severe frost, to cover their heads and stems.

It is the first sort which requires the most care, being much tenderer than any of the other, for they will endure the cold very well, without much care, after they have acquired strength; for as these lose their leaves in the winter, the frost will not have so much force upon them as of the first sort, whose leaves are frequently tender toward the end of the shoots, especially when they grow freely, or shoot late in the autumn.

MAHALEB. See CERASUS.

MALA INSANA. See MELONGENA.

MALLOW. See MALVA.

MALLOW-TREE. See LAVATERA.

MALOPE. Bastard Mallow.

The CHARACTERS are,

The flower, which is shaped like that of the Mallow, hath a double empalement, the outer being composed of three heart-shaped leaves, and the inner is of one leaf cut into five segments; the flower is of one petal, divided into five parts at the bottom, where they are joined, but so near the bottom as to have the appearance of five petals. In the center arises the pointal, having a great number of stamina surrounding it, which are joined closely, and form a sort of column. The pointal afterward becomes a fruit composed of many cells, which are collected into a head, in each of which is lodged a single seed.

We have but one SPECIES of this plant, viz.

MALOPE (*Malacoides*) foliis ovatis crenatis glabris. Lin. Hort. Cliff. 347. Bastard Mallow, with oval smooth leaves, which are notched.

This plant was by Dr. Tournefort separated from the Mallow, and made a distinct genus, by the title of *Malacoides*; but Dr. Linnæus has altered the title of this for *Malope*, being an enemy to all names which are compounded of *oides*.

The whole plant has greatly the appearance of the Mallow, but differs from it, in having the cells collected into a button, somewhat like a Blackberry; the branches spread, and lie almost flat upon the ground, extending themselves a foot or more each way. The flowers are produced singly upon long foot-stalks, which arise from the wings of the leaves, which are in shape and colour like those of the Mallow.

This is propagated by seeds, which should be sown in the place where they are designed to remain, for they do not bear transplanting well. If these seeds are sown upon a warm border in August, the plants will frequently stand through the winter, and flower early the following season, so that good seeds may be obtained; for those which are sown in the spring, rarely ripen seeds the same year in England; and these plants being large, are often destroyed in winter, unless they are sheltered under a frame; it seldom continues longer than two or three years, so that young plants should be annually raised.

MALPIGHIA. Plum. Nov. Gen. 46. tab. 36. Lin. Gen. Plant. 38. Barbadoes Cherry, vulgò.

The CHARACTERS are,

The flower hath a small permanent empalement of five leaves, which are closed together. It hath two oval melonous glands, adbering to the small leaves within and without. It has five kidney-shaped petals, which are concave, and spread open, having long narrow tails, and ten broad awl-shaped stamina, which are erect, terminated by heart-shaped summits. It has a small roundish germen, supporting three slender styles, crowned by obtuse stigmas. The germen afterward turns to a large furrowed globular berry with one cell, inclosing three rough stony seeds, which are angular.

S L

This

M A L

This genus of plants is ranged in the third section of Linnæus's tenth class, intitled Decandria Trigynia, which includes the plants whose flowers have ten stamina and three styles.

The SPECIES are,

1. MALPIGHIA (*Glabra*) foliis ovatis integerrimis glabris, pedunculis umbellatis. Hort. Cliff. 169. *Malpighia with smooth, oval, entire leaves, and umbellated foot-stalks.* Cerasus Jamaicaensis, fructu tetrapireno. Hort. Amst. 1. p. 145. *Jamaica Cherry with a fruit having four seeds, commonly called Barbadoes Cherry.*
2. MALPIGHIA (*Punicifolia*) foliis ovato-lanceolatis, acuminatis, glabris, pedunculis umbellatis. *Malpighia with oval, spear-shaped, smooth leaves, ending in acute points, and umbellated foot-stalks.* Malpighia mali punici facie. Plum. Nov. Gen. 46. *Malpighia with the appearance of Pomegranate.*
3. MALPIGHIA (*Incana*) foliis lanceolatis subtus incanis, pedunculis umbellatis alaribus. *Malpighia with spear-shaped leaves, hoary on their under side, and umbellated foot-stalks, proceeding from the wings of the stalk.*
4. MALPIGHIA (*Urens*) foliis cordato-lanceolatis, setis decumbentibus rigidis, racemis lateralibus. *Malpighia with spear heart-shaped leaves, having rigid declining bristles, and bunches of flowers proceeding from the sides of the stalks.* Malpighia latifolia, folio subtus spinoso. Plum. Nov. Gen. 46. *Broad-leaved Malpighia, with spines growing on the under side of the leaf.*
5. MALPIGHIA (*Nitida*) foliis ovatis acutis glabris, pedunculis umbellatis alaribus terminalibusque. *Malpighia with oval, smooth, acute-pointed leaves, and umbellated foot-stalks, proceeding from the sides and at the ends of the branches.*
6. MALPIGHIA (*Paniculata*) foliis oblongo-cordatis acuminatis glabris, pedunculis paniculatis, alaribus terminalibusque. *Malpighia with oblong, heart-shaped, smooth leaves, ending in acute points, and paniculated foot-stalks proceeding from the sides and ends of the branches.* Apocynum fruticosum, folio oblongo acuminato, floribus racemosis. Sloan. Cat. 89. *Shrubby Dogbane with an oblong acute-pointed leaf, and flowers growing in clusters.*
7. MALPIGHIA (*Angustifolia*) foliis lineari-lanceolatis, setis decumbentibus rigidis, pedunculis umbellatis alaribus. *Malpighia with linear spear-shaped leaves, rigid declining bristles, and foot-stalks having umbels of flowers proceeding from the sides of the branches.* Malpighia angustifolia, folio subtus spinoso. Plum. Nov. Gen. 46. *Narrow-leaved Malpighia with spines under the leaves.*
8. MALPIGHIA (*Illicifolia*) foliis lanceolatis dentato-spinosis subtus hispidis. Lin. Sp. Plant. 426. *Malpighia with spear-shaped leaves, indented and prickly, whose under sides are set with spiny hairs.* Malpighia angustis & acuminatis aquifolii foliis. Plum. Nov. Gen. 46. *Malpighia with narrow and acute-pointed Holly leaves.*
9. MALPIGHIA (*Lucida*) foliis oblongo-ovatis obtusis glabris, pedunculis racemosis alaribus. *Malpighia with oblong oval leaves, which are obtuse and smooth, and branching foot-stalks of flowers proceeding from the sides of the branches.*
10. MALPIGHIA (*Coccigrya*) foliis subovatis dentato-spinosis, pedunculis unifloris. *Malpighia with leaves nearly oval, indented, and prickly, and foot-stalks with one flower.* Malpighia humilis, ilicis cocci-glandiferæ foliis. Plum. Nov. Gen. 46. *Low Malpighia with leaves like the Kermes Oak.*

The first sort is commonly cultivated in the West-Indies for the sake of its fruit; this tree usually grows to the height of sixteen or eighteen feet, having a slender stem, covered with a light brown bark. The leaves are produced opposite; they are oval, smooth, ending in acute points, and continue all the year. The flowers are produced in bunches upon pretty long foot-stalks, which come out from the side and at the end of the branches; these are composed of five roundish petals, which are of a Rose colour, joined at their base. The flowers are succeeded by red fruit, shaped like those of the small wild Cherry,

M A L

and of the same size, having several furrows, each inclosing four angular furrowed stones, surrounded by a thin pulp, which has an agreeable acid flavour; the fruit of this often ripens in England.

The second sort grows naturally in Jamaica; this rises with a shrubby stalk ten or twelve feet high, dividing into several slender spreading branches, covered with a light brown bark, garnished with oval, spear-shaped, smooth leaves placed opposite, ending in acute points. The flowers are produced in small umbels at the end of the branches, upon short foot-stalks; they are of a pale Rose colour, and composed of five obtuse concave petals which are indented, having long narrow tails, by which they are joined; these spread open, and in the center is situated the roundish germen, supporting three styles, attended by ten stamina which spread asunder. The germen afterward turns to a roundish pulpy berry with many furrows, red when ripe, inclosing three or four hard angular seeds. The fruit of this sort is eaten by the inhabitants of the isles in America.

The third sort grows naturally at Campeachy, from whence it was sent me by the late Mr. Robert Millar. This rises with a strong woody stalk eighteen or twenty feet high, dividing into many branches, covered with a brown spotted bark, garnished with spear-shaped leaves placed opposite, which are hoary on their under side. The flowers come out in umbels from the side of the branches; they are of a Rose colour, and are succeeded by oval channelled fruit, like those of the former sort.

The fourth sort grows naturally in Jamaica, from whence the late Dr. Houstoun sent me the seeds. This rises with a woody stalk from fifteen to eighteen feet high, dividing into many pretty strong branches, which are furrowed, and covered with a brown bark. The leaves are from three to four inches long, and one broad at their base, where they are rounded in form of a heart, lessening gradually to the point; they are covered on their under sides with stinging bristly hairs so closely, as to render it very troublesome to handle them, for these hairs fasten themselves into the flesh, and are difficult to get out again. The flowers are produced in umbels from the side of the branches; they are of a light purple colour, and shaped like those of the other species; they are succeeded by oval furrowed fruit like that of the former sort. This is called in the West-Indies, Couhage, or Cowitch Cherry.

The fifth sort grows naturally at Carthagen in New Spain, from whence the late Dr. Houstoun sent me the seeds. This rises with a shrubby stalk about ten feet high, covered with a light brown spotted bark, branching out regularly at the top on every side; the leaves are oval, smooth, and end in acute points, standing opposite, of a light green on the upper side, but paler on the under. The flowers come out from the side of the stalks in small umbels, standing erect; the foot-stalks of the umbels are scarce an inch long. They are of a pale blush colour, shaped like those of the former sorts; these are succeeded by roundish furrowed berries with a red skin, covering three hard angular seeds.

The sixth sort grows naturally in Jamaica, from whence the late Dr. Houstoun sent the seeds to England. This rises with several slender shrubby stalks from five to six feet high, garnished with oblong heart-shaped leaves, four inches long and one inch and a quarter broad at the base, where they are rounded in two heart-shaped lobes, gradually diminishing to the point; they are smooth, and of a pale yellowish green, placed opposite. The flowers are produced in loose panicles from the side and at the end of the branches; they are of a light purple colour, shaped like those of the other species, but smaller; the fruit is more pointed, and not so much furrowed.

The seventh sort was sent me from the island Barbuda: this rises with a shrubby stalk seven or eight feet high, covered with a bright purplish bark which is spotted and furrowed, dividing toward the top into several

several smaller branches, garnished with narrow spear-shaped leaves, about two inches long and a quarter of an inch broad, of a lucid green on their upper side, but of a russet brown on their under, where they are closely armed with stinging bristles, which fasten themselves into the flesh or clothes of those who touch them; these leaves are placed opposite. The flowers are produced from the side and at the end of the branches in small umbels; they are of a pale purple colour, of the same form of the other species, but smaller; and are succeeded by small, oval, furrowed fruit, of a dark purple colour when ripe.

The eighth sort was sent me from the island Barbuda in the West-Indies, where it grows naturally. This rises with a strong woody stem from fifteen to twenty feet high, dividing into many spreading branches, covered with a gray bark, garnished with oblong oval leaves of a firm consistence; they are about an inch long, and half an inch broad, rounded at their ends, of a lucid green, and placed opposite. The flowers come out from the side, and also at the end of the branches, upon pretty long foot-stalks, which branch in form of a racemus, or long bunch. They are of the same form with those of the other species, but vary in their colour, some of them being of a bright red, and others of an Orange colour in the same bunch; these are succeeded by small oval berries, which are less furrowed than those of the other species, and, when ripe, change to a dark purple colour.

The ninth sort grows naturally in the island of Cuba, where the late Dr. Houstoun found it in plenty. This rises with a shrubby stalk to the height of seven or eight feet, sending out branches the whole length, which are covered with a gray bark, garnished with narrow prickly leaves like those of the Holly, which have many stinging bristles on their under side. The flowers are produced in small clusters from the side of the branches, they are of a pale blush colour, and shaped like those of the other species, but smaller; the fruit is more pointed than those of the common sort, and turns to a dark purple colour when ripe.

The tenth sort grows naturally near the Havanna, from whence the late Dr. Houstoun sent the seeds. This is a very low shrub, seldom rising more than two or three feet high; the stalk is thick and woody, as are also the branches, which come out on every side from the root upward; they are covered with a rough gray bark, garnished with lucid leaves half an inch long, and almost as much broad; they appear as if cut at their ends, where they are hollowed in, and the two corners rise like horns ending in a sharp thorn, as do also the indentures on the sides. The flowers come out from the side of the branches, upon foot-stalks an inch long, each sustaining one small pale blush flower, of the same form with those of the other species; the fruit is small, conical, and furrowed, changing to a purple red colour when ripe.

There are two other species of this genus, which have been lately introduced from America, but as neither of them have yet flowered here, so I have not enumerated them; and if those warm parts of America were searched by persons of skill, there might be many more species discovered; for from a large number of imperfect specimens which were sent me from the Spanish West-Indies, I have selected many which have the appearance of the other species of this genus, but as they are without flowers or fruit, they cannot be ascertained.

The fruit of several of the species here mentioned, are promiscuously gathered and eaten by the inhabitants of the countries where they naturally grow; but the first sort is cultivated in some of the islands for its fruit, though that is but indifferent: the pulp which surrounds the stones is very thin, but has a pleasant acid flavour, which renders it agreeable to the inhabitants of those warm countries, where, to supply the want of those Cherries which are culti-

vated in Europe, they are obliged to eat the fruit of these shrubs.

These plants are preserved in the gardens of those persons who are so curious in botanical studies, as to erect hot-houses for maintaining foreign plants: and where there are such conveniencies, these plants deserve a place; because they retain their leaves all the year, and commonly continue flowering from December to the end of March, when they make a fine appearance at a season, when there is a scarcity of other flowers, and many times they produce ripe fruit here. Those sorts whose leaves are armed with stinging bristles, like the Cowitch, are the least worthy of a place in stoves, because they are so troublesome to handle, nor do their flowers make so good an appearance as many of the other sorts. The tenth sort is the most valuable for its flowers, which are produced in larger bunches than those of any of the other, and there being flowers of different colours in the same bunches, they make a fine variety; and this sort grows more like a tree than the others, the leaves are also of a stronger consistence and of a lucid green.

As these plants are natives of the warmest parts of America, they will not live through the winter in England, unless they are preserved in a warm stove; but when the plants have obtained strength, they may be exposed in the open air in a warm situation, from the middle or latter end of June, till the beginning of October, provided the weather continues so long mild; and the plants so treated, will flower much better than those which are constantly kept in a stove.

They are all propagated by seeds, which must be sown upon a good hot-bed in the spring; and when the plants are fit to transplant, they must be each put into a separate small pot filled with rich earth, and plunged into a hot-bed of tanners bark, and must be treated in the same manner as hath been directed for other tender plants of the same country; and for the two first winters, it will be proper to keep them in the bark-bed in the stove; but afterward they may be placed upon stands in the dry stove in winter, where they may be kept in a temperate warmth, in which they will thrive much better than in a greater heat; these must be watered two or three times a week, when they are placed in the dry stove, but it must not be given to them in large quantities.

MALT-DUST is accounted a great enricher of barren ground; it contains in it a natural heat and sweetness, which gives the earth whereon it is laid a proper fermentation, as those who live in malting countries have found by experience.

Some are of opinion, that there is not a greater sweetener than Malt-dust, where the grounds are natural clay, and have contracted a sourness and austerity, whether by reason of its having lain long untilld and unexposed to the air, or by reason of water having stood long thereon.

MALVA. Tourn. Inst. R. H. 94. tab. 23. Lin. Gen. Plant. 751. [so called of *μαλαρίζω*, or *μαλάσσω*, to soften, because it is good to soften the belly.] Mal-lows; in French, *Mauve*.

The CHARACTERS are,

The flower has a double empalement; the outer is composed of three spear-shaped leaves, and is permanent; the inner is of one leaf, cut into five broad segments at the brim. The flower is, according to Tournefort, Ray, &c. of one petal; but according to Linnaeus, it has five; they are joined at the base, and spread open, and fall off joined. It has a great number of stamina which coalesce at bottom in a cylinder, but spread open above, and are inserted in the petal, terminated by kidney-shaped summits. In the center is situated an orbicular germen supporting a short cylindrical style, with many bristly stigmas the length of the style. The empalement afterward turns to several capsules, which are joined in an orbicular depressed head fastened to the column, opening on their inside, each containing one kidney-shaped seed.

This

This genus of plants is ranged in the fifth section of Linnæus's sixteenth class, intitled Monodelphia Polyandria, which contains those plants whose flowers have many stamina joined with the style in one body.

The SPECIES are,

1. MALVA (*Sylvestris*) caule erecto herbaceo, foliis septem lobatis acutis pedunculis petiolisque pilosis. Lin. Sp. Plant. 969. *Mallow with an erect herbaceous stalk, with seven acute lobes to the leaves, and hairy foot-stalks both to the leaves and flowers.* Malva sylvestris, folio sinuato. C. B. P. 314. *Wild Mallow with a sinuated leaf.*
2. MALVA (*Rotundifolia*) caule prostrato, foliis cordato-orbiculatis obsolete quinquelobis, pedunculis fructiferis declinatis. Lin. Sp. 969. *Mallow with prostrate stalks, roundish heart-shaped leaves with five obsolete lobes, and the foot-stalks of the fruit declining.* Malva vulgaris, flore minore, folio rotundo. J. B. 2. p. 949. *Common Mallow with a small flower and a round leaf.*
3. MALVA (*Orientalis*) annua, caule erecto herbaceo, foliis lobatis obtusis & crenatis. *Annual Mallow with an erect herbaceous stalk, and obtuse lobed leaves which are crenated.* Malva orientalis erectior, flore magno suavè rubente. Tourn. Cor. 3. *Eastern Mallow with a more upright stalk, and a large, soft, red flower.*
4. MALVA (*Crispa*) caule erecto, foliis angulatis crispis, floribus axillaribus glomeratis. Lin. Sp. 970. *Mallow with an erect stalk, angular curled leaves, and flowers in clusters on the side of the stalks.* Malva foliis crispis. C. B. P. 315. *Furrowed Mallow.*
5. MALVA (*Verticillata*) caule erecto, foliis angulatis, floribus axillaribus glomeratis sessilibus, calycibus scabris. Vir. Cliff. 356. *Mallow with an erect stalk, angular leaves, and flowers growing in whorls at the wings of the stalks.*
6. MALVA (*Chinensis*) annua, caule erecto herbaceo, foliis suborbiculatis obsolete quinquelobatis, floribus confertis alaribus sessilibus. *Annual Mallow with an erect, herbaceous, single stalk, leaves almost round, with five indented lobes, and flowers growing in clusters, which sit close to the stalks.* Malva Sinensis erecta, flosculis albis minimis. Boerh. Ind. alt. *Upright annual China Mallow, with very small white flowers.*
7. MALVA (*Cretica*) caule erecto ramoso hirsuto, foliis angulatis, floribus alaribus pedunculis brevioribus. *Mallow with an erect, branching, hairy stalk, angular leaves, and flowers proceeding from the wings of the stalks, which grow upon shorter foot-stalks.* Malva Cretica annua altissima, flore parvo ad alas umbellato. Tourn. Cor. 2. *Tallest annual Mallow of Crete, with small flowers growing in umbels on the sides of the stalk.*
8. MALVA (*Peruviana*) caule erecto herbaceo, foliis lobatis, spicis secundis axillaribus feminibus denticulatis. Lin. Sp. Plant. 968. *Mallow with an erect herbaceous stalk, leaves having lobes, and spikes of flowers in fruitful clusters proceeding from the sides of the stalks, and indented seeds.*
9. MALVA (*Alcea*) caule erecto, foliis multipartitis scabriusculis. Hort. Cliff. 347. *Mallow with an erect stalk, and rough leaves divided into many parts.* Alcea tenuifolia crispa. J. B. 2. 953. *Narrow-leaved curled Vervain Mallow.*
10. MALVA (*Moschata*) foliis radicalibus reniformibus incis, caulinis quinque partitis pinnato-multifidis. Hort. Upsal. 202. *Mallow with kidney-shaped lower leaves which are cut, and those on the stalks divided into five parts, ending in winged points.* Alcea folio rotundo laciniato. C. B. P. 316. *Round cut-leaved Vervain Mallow.*
11. MALVA (*Ægyptia*) foliis palmatis dentatis, corollis calyce minoribus. Lin. Sp. Plant. 690. *Mallow with hand-shaped indented leaves, and petals less than the em-palement.* Alcea Ægyptia, geranii folio. Juss. *Egyptian Vervain Mallow with a Crane's-bill leaf.*
12. MALVA (*Bryonifolia*) foliis palmatis scabris, caule tomentoso fruticoso, pedunculis multifloris. Prod. Leyd. 356. *Mallow with rough hand-shaped leaves, a shrubby woolly stalk, and foot-stalks with many flowers.* Althæa frutescens bryoniæ folio. C. B. P. 316. *Shrubby Vervain Mallow with a Briony leaf.*

13. MALVA (*Tournefortia*) foliis radicalibus quinque partitis, trilobis linearibus, pedunculis folio caulino longioribus, caule procumbente. Amœn. Acad. 4. p. 283. *Mallow with cut leaves having three lobes, which are linear, and a declining stalk.* Alcea maritima Galloprovincialis, geranii folio. Tourn. Inst. 98. *Maritime Vervain Mallow of Provence, with a Crane's-bill leaf.*

14. MALVA (*Capensis*) foliis subcordatis laciniatis hirsutis, caule arborescente. *Mallow with hairy cut leaves, almost heart-shaped, and a tree-like stalk.* Malva Africana frutescens, flore rubro. Hort. Amst. 2. p. 171. *African shrubby Mallow with a red flower.*

15. MALVA (*Americana*) foliis cordatis crenatis, floribus lateralibus solitariis, terminalibus spicatis. Prod. Leyd. 359. *Mallow with heart-shaped crenated leaves, and flowers growing singly from the sides of the stalks, and in spikes at the top.* Althæa Americana, pumila, flore luteo spicato. Breyn. Cent. 124. *Low American Marsh-mallow, with a yellow spiked flower.*

The two first sorts are found wild in most parts of England, so are rarely cultivated in gardens. The first is the sort commonly used in medicine, with which the markets are supplied by the herbfolks, who gather it in the fields. These are both so well known, as to need no description. There is a variety of the first with white flowers, which continues the same from seeds; but as it only differs in the colour of the flower, so it cannot be reckoned a distinct species.

The third sort was discovered by Dr. Tournefort in the Levant, this is an annual plant with an erect stalk; the flowers are larger than those of the common sort, and are of a soft red colour. This is preserved in some curious gardens for the sake of variety.

The fourth sort is annual; this rises with an upright stalk four or five feet high; the leaves are curled on their edges, for which variety it is preserved in gardens.

The fifth sort was discovered first by Dr. Tournefort, and afterward by Dr. Sherard, in the Levant, who sent the seeds to several gardens, where the plants have produced flowers and seeds; which having scattered in those gardens so plentifully, as to become as common as our native sorts.

The sixth sort was formerly sent from China as a pot-herb, and hath been cultivated in some curious gardens in England; though it is not likely to obtain here as an esculent plant, since we have many others which are preferable to it for that purpose. This is an annual plant, which will propagate itself fast enough, provided it be permitted to scatter its seeds, when they seldom fail to grow, and are often very troublesome when they have gotten possession of the ground.

The seventh sort grows naturally in Crete; this plant is annual, the stalks rises rather higher than that of our common Mallow, and the branches extend farther, and are in greater plenty; the leaves are angular, and the flowers stand on short foot-stalks. This will be very common, provided the seeds are permitted to scatter.

The eighth sort grows naturally in Peru, from whence the seeds were sent to the Royal Garden at Paris, by Mr. Joseph de Jussieu. This is an annual plant, rising with an upright branching stalk near two feet high, garnished with broad hairy leaves, having three lobes. The flowers grow in spikes from the wings of the stalks; they are small, of a pale blue, and set very closely on the spikes. These appear in June, and are succeeded by seeds, which, if permitted to scatter, will come up plentifully the following spring without care.

The ninth sort is the common Vervain Mallow, which is found growing naturally near London. It is a biennial plant; the stalks rise higher than those of the former, the leaves are cut into obtuse lobes which are indented. The flowers are large, appearing in June and July, and the seeds ripen in autumn.

The tenth sort differs from the ninth, in having taller hairy stalks, and the leaves being kidney-shaped, and

M A L

and finely cut into narrow segments. This grows naturally in the middle counties of England, and about Paris.

The eleventh sort was sent from Egypt to the Royal Garden at Paris, and hath since been communicated to many other gardens. This is an annual plant, whose stalks are about a foot long; they are smooth, and decline toward the ground. The leaves stand upon pretty long foot-stalks, they are shaped like a hand, having five divisions which join at their base to the foot-stalk, and are indented on their sides. The flowers come out single from the wings of the stalk, and at the top in clusters; they have pretty large acute empalements; the flowers are small, and of a pale blue colour. These appear in June, and the seeds ripen in autumn.

The twelfth sort grows naturally in Spain; this rises with a shrubby woolly stalk four or five feet high, sending out branches on every side, garnished with angular woolly rough leaves; the foot-stalks arise from the wings of the leaves, each supporting four or five flowers of a bright purple colour, shaped like those of the common Mallow, which appear in July, and the seeds ripen in autumn. This sort seldom continues more than two or three years, but if the seeds are permitted to scatter, young plants will come up the following spring.

The thirteenth sort grows naturally in the south of France; this is an annual plant, which has some resemblance of the former, but the stalks are longer and more branched; the leaves are cut into five obtuse lobes almost to the bottom, and these are deeply cut on their side. The flowers stand upon very long foot-stalks; the empalement of the flower is large, prickly and acute-pointed; the flowers are blue, and larger than those of the other sort. It flowers and ripens its seeds about the same time.

The fourteenth sort grows naturally at the Cape of Good Hope; this rises with a woody stalk ten or twelve feet high, sending out branches from the side the whole length; the stalks and branches are closely covered with hairs, and are garnished with hairy leaves, which are indented on the sides, so as to have the appearance of a trilobate leaf; these on the young plants are three inches long and two broad at their base, but as the plants grow older, they are scarce half that size. The flowers come out from the side of the branches, upon foot-stalks an inch long; they are of a deep red colour, and shaped like those of the common Mallow, but are smaller. This plant continues flowering great part of the year, which renders it valuable.

There are two other varieties of this plant, which have been mentioned by some authors as distinct species. The first is, *Alcea Africana frutescens, grossulariæ folio ampliore, unguibus florum atro-rubentibus*. Act. Phil. 1729. *Shrubby African Vervain Mallow, with a larger Gooseberry leaf, and the bottoms of the flower of a dark red*. The other is, *Alcea Africana frutescens, folio grossulariæ flore parvo rubro*. Boerh. Ind. alt. 1. 271. *Shrubby African Vervain Mallow, with a Gooseberry leaf, and a small red flower*. The leaves of the last appear very different from either of the other, being deeply divided into three lobes, which are also deeply indented, so that any person upon seeing it would suppose it to be a different species; but I have frequently raised all these, with some other intermediate varieties, from the seeds of one plant.

This plant is easily propagated by seeds, which, if sown in a common border in the spring, the plants will come up; but as it is too tender to live abroad in the winter, so when the plants are three or four inches high, they should be each planted into a separate pot of light fresh earth, placing them in the shade till they have taken fresh root; then they may be removed to a sheltered situation, intermixing them with other hardy exotic plants, where they may remain till autumn; when the frost comes on they should be removed into the green-house, and after-

M A L

ward treated in the same way as the hardy plants from the same country, always allowing them plenty of free air in mild weather.

The fifteenth sort grows naturally in most of the islands in the West-Indies. This is an annual plant, which rises about a foot high, sending out a few short branches from the side, which are woolly, and garnished with heart-shaped woolly leaves which are crenated on their edges, and are placed alternately upon pretty long foot-stalks. The flowers are produced singly from the side of the stalk, and in a close spike at the top; they are small, and of a pale yellow colour. They appear in July, and the seeds ripen in autumn.

This is propagated by seeds, which must be sown upon a hot-bed in the spring; and when the plants are fit to remove, they should be each planted in a separate small pot filled with light fresh earth, and plunged into a new hot-bed, shading them until they have taken fresh root; then they must have free air admitted to them in proportion to the warmth of the season, and the latter end of June they may be placed in the open air in a sheltered situation, where they will flower and produce ripe seeds.

The seeds of the other species should be sown the end of March, upon a bed of fresh light earth, and when the plants are up three or four inches high, they should be transplanted where they are designed to be continued, allowing them a good distance; for if they are planted too close, they do not appear so well; but they are best when intermixed with other flowers of the same growth, where they afford an agreeable variety.

These seeds may also be sown in August, for the plants will endure the greatest cold of our climate, if placed on a dry soil, and will grow larger, and flower sooner than those sown in the spring; or if the seeds are permitted to scatter, they will come up as the former sorts, and thrive equally well.

MALVA ARBOREA. See LAVATERA.

MALVA ROSEA. See ALCEA.

MALUS. The Apple-tree.

The CHARACTERS are,

The empalement of the flower is of one leaf, cut into five segments. The flower consists of five leaves, which expand in form of a Rose, whose tails are inserted into the empalement. The fruit is hollowed about the foot-stalk, is for the most part roundish, and umbellated at the top; it is fleshy, and divided into five cells or partitions, in each of which is lodged one oblong seed.

Dr. Linnæus has joined the Pear, Apple, and Quince together, making them all of the same genus, and has reduced all the varieties of each to one species. The Apple he distinguishes by the title of *Pyrus foliis serratis, pomis basi concavis*. Hort. Cliff. i. c. *Pear with sawed leaves, and the Apple hollow at the base*. But where the fruit is admitted as a distinguishing character of the genus, the Apple should be separated from the Pear, this distinction being founded in nature; for these fruits will not take by budding or grafting upon each other, though it be performed with the utmost care. Indeed I have sometimes succeeded so far, as to have the bud or graft of an Apple shoot when grafted on a Pear, but they soon decayed, notwithstanding all possible care was taken of them; therefore I shall beg leave to continue the separation of the Apple from the Pear, as hath been always practised by the botanists before his time.

The SPECIES are,

1. MALUS (*Sylvestris*) foliis ovatis serratis, caule arboreo. *Apple with oval sawed leaves, and a tree-like stalk*. Malus sylvestris, fructu valde acerbo. Tourn. Inst. R. H. 635. *Wild Apple with a very sour fruit, commonly called Crab*.
2. MALUS (*Coronaria*) foliis serrato-angulosis. *Apple with angular sawed leaves*. Malus sylvestris Virginiana, floribus odoratis, Cat. Hort. *Wild Crab of Virginia, with a sweet-scented flower*.
3. MALUS (*Pumila*) foliis ovatis serratis, caule fruticoso. *Apple with oval sawed leaves and a shrubby stalk*. Malus

S M

pumila

pumila quæ potius frutex quam arbor. C. B. P. 433. *Dwarf Apple, which is rather a shrub than a tree, commonly called Paradise Apple.*

Of the first sort there are two varieties of fruit, one is white, and the other purple toward the sun, but these are accidental variations. There is also a variety of this with variegated leaves, which has been propagated in some of the nurseries near London; but when the trees grow vigorous, their leaves soon become plain.

The second sort grows naturally in most parts of North America, where the inhabitants plant them for stocks to graft other sorts of Apples upon; the leaves of this are longer and narrower than any of the other sorts, and are cut into two acute angles on their sides. The flowers of this have a fragrant odour, which perfumes the American woods at the time they appear. The third sort is undoubtedly a distinct species from all the others, for it never rises to any height; the branches are weak, scarce able to support themselves, and this difference is permanent when raised from seeds.

I have not distinguished the Apples from the Crab, as distinct species, though I have never seen any Apples produced from the seeds of Crabs. I shall next mention a few of those sorts of Apples which have been introduced from France, which were most of them grafted on Paradise stocks, so were for some time much esteemed, and shall mention those of our own growth afterward.

There is also a sort of Apple, called the Fig Apple, which is common to England and North America, but the fruit is not greatly esteemed; however, as some persons are fond of variety, so I have mentioned it.

Pomme de Rambour. The Rambour is a very large fruit, of a fine red next the sun, and striped with a pale or yellowish green. This ripens very early, commonly about the end of August, and soon grows meally, therefore is not esteemed in England.

Pomme de Courpendu, the hanging body. This is a very large Apple, of an oblong figure, having some irregular rising or angles, which run from the base to the crown; it is of a red cast on the side toward the sun, but pale on the other side; the foot-stalk is long and slender, so that the fruit is always hanging downward, which occasioned the French gardeners to give it this name.

The Rennette-blanche, or White Renette, or French Renette. This is a large fine fruit, of a roundish figure, and of a pale green, changing a little yellowish when ripe, having some small gray spots; the juice is sugary, and it is good for eating or baking; it will keep till after Christmas sound.

The Rennette-grise. This is a middle sized fruit, shaped like the Golden Renette, but is of a deep gray colour on the side next the sun, but on the other side intermixed with yellow; it is a very juicy good Apple, of a quick flavour. It ripens in October, and will not keep long.

Pomme d'Api. This is a small hard fruit, of a bright purple colour on the side next the sun, and of a yellowish green on the other side; it is a very firm fruit, but hath not much flavour, so is only preserved by some persons by way of curiosity. It keeps a long time sound, and makes a variety in a dish of fruit.

Le Calville d'Automne, the Autumn Calville. This is a large fruit of an oblong figure, of a fine red colour toward the sun. The juice is vinous, and much esteemed by the French.

Fenouillat ou Pomme d'Anis, the Fennel, or Anise Apple. This is a middle sized fruit, a little longer than a Golden Pippin, of a grayish colour. The pulp is tender, and has a spicy taste like Anise-seed; the wood and the leaves are whitish.

Pomme Violette, the Violet Apple. This is a pretty large fruit, of a pale green, striped with deep red to the sun. The juice is sugary, and has a flavour of Violets, which occasioned the name.

The Crab, which is the first sort here mentioned, has

been generally esteemed as the best stock for grafting Apples upon, being very hardy, and of long duration; but of late years there have been few persons who have been curious enough to raise these stocks, having commonly sown the kernels of all sorts of cyder Apples for stocks without distinction, as these are much easier to procure than the other; so the gardeners generally call all those Crabs, which are produced from the kernels of any sort of Apple which has not been grafted; but were the kernels of the Crabs sown, I should prefer those for stocks, because they are never so luxuriant in their growth as those from Apple kernels, and they will continue longer sound; beside, these will preserve some of the best sort of Apples in their true size, colour, and flavour; whereas the other free stocks produce larger fruit, which are not so well tasted, nor will they keep so long.

The Paradise Apple for some years past was greatly esteemed for stocks, to graft or bud the other sorts upon; but these are not of long duration, nor will the trees grafted upon them ever grow to any size, unless they are planted so low as that the cion may strike root into the ground, when it will be equal to no stock; for as the graft will draw its nourishment from the ground, so the stocks will become useless after; therefore it is only by way of curiosity, or for very small gardens, that these stocks are proper, since there can never be expected any considerable quantity of fruit from such trees.

These trees have been much more esteemed in France, where they were frequently brought to the table in the pots, growing with their fruit upon them; but this being only a curiosity, it never obtained much in England, so that the gardeners do not propagate many of them here at present.

There is another Apple, which is called the Dutch Paradise Apple, much cultivated in the nurseries for grafting Apples upon, in order to have them dwarfs; and these will not decay or canker as the other, nor do they stint the grafts near so much, so are generally preferred for planting espaliers or dwarfs, being easily kept within the compass usually allotted to these trees.

Some persons have also made use of the Codlin stocks to graft Apples upon, in order to make them dwarf; but the fruit which are produced on such trees are not so firm, nor do they last near so long as those upon Crab stocks; therefore the winter fruits should never be grafted upon them.

The Virginian Crab-tree with sweet flowers, is often preserved by such persons as are curious in collecting great variety of trees; it may be propagated by budding or grafting it upon the common Crab or Apple-tree, but it is somewhat tender while young; wherefore it should be planted in a warm situation, otherwise it will be subject to suffer by an extreme hard winter. The flowers of this tree are said to be exceeding sweet in Virginia, where it grows in the woods in great plenty; but I could not observe much scent in some of them which have flowered in England, so that I am in doubt whether the sort at present in the gardens is the very same with that of Virginia; or perhaps it may have degenerated by sowing the seeds, which is the way it was first obtained in England.

The Fig Apple is supposed by many persons to be produced without a previous flower. But this opinion is rejected by more curious observers, who affirm, there is a small flower precedes the fruit, which is very fugacious, seldom continuing above a day or two. Now, which of these opinions is the right, I have not, as yet, had an opportunity to determine, not having a tree in my own possession which is arrived at maturity to produce fruit; though it might reasonably be expected, that such who have had trees of this kind several years, might have determined this point long before this time.

I remember an account of a tree of this kind, mentioned in a letter from New England, written by Paul Dudley, Esq; to the Royal Society, and published in the Philosophical Transactions, N^o 385. which was exceeding

M A L

exceeding large, and produced great quantities of fruit, without any previous flowers; but it grew at some distance from his habitation, and he having no other opportunity to observe it strictly himself, but by visiting the place two or three times about the season of flowering, and not being apprized of the sudden decay of the flowers, they might easily be supposed to have appeared and dropped off, between the times of his visiting the place.

The other sorts which are above-mentioned, are what have been introduced from France, but there are not above two or three of them, which are much esteemed in England, viz. the French Renette, the Renette-grise, and the Violet Apple; the other being early fruit, which do not keep long, and their flesh is generally mealy, so they do not deserve to be propagated, as we have many better fruits in England: but as there may be some persons who are willing to have all the sorts, I have mentioned them here for their instruction; but I shall next put down those sorts of Apples which are best esteemed in England, placing them in the order according to their time of ripening.

The first Apple which is brought to the markets, is the Codlin. This fruit is so well known in England, that it is needless to describe it.

The next is the Margaret Apple: this fruit is not so long as the Codlin, of a middling size; the side next the sun changes to a faint red, when ripe; the other side is of a pale green; the fruit is firm, of a quick pleasant taste, but doth not keep long.

The Summer Pearmain is an oblong fruit, striped with red next the sun; the flesh is soft, and in a short time is mealy, so that it is not greatly esteemed.

The Kentish Fill Basket is a species of Codlin, of a large size, and somewhat longer shaped than the Codlin; this ripens a little later in the season, and is generally used for baking, &c.

The Transparent Apple: this was brought to England a few years since, and was esteemed a curiosity; it came from Peterburgh, where it is affirmed to be so transparent, as that the kernels may be perfectly seen, when the Apple is held to the light; but, in this country, it is a mealy insipid fruit, so not worth propagating.

Loan's Pearmain: this is a beautiful fruit, being of a middling size; the side next the sun is of a beautiful red, and striped with the same colour on the other; the flesh is vinous, but as it soon grows mealy, it is not greatly esteemed.

The Quince Apple: this is a small fruit, seldom larger than the Golden Pippin, but is in shape like the Quince, especially toward the stalk; the side next the sun is of a russet colour, on the other side inclining to yellow: this is an excellent Apple for about three weeks in September, but will not keep much longer.

The Golden Renette is a fruit so well known in England, as to need no description; this ripens about Michaelmas, and for about a month is a very good fruit, either for eating raw or baking.

The Aromatic Pippin is also a very good Apple: it is about the size of a Nonpareil, but not so flat, it is a little longer; the side next the sun is of a bright russet colour; the flesh is breaking, and hath an aromatic flavour. It ripens in October.

The Hertfordshire Pearmain, by some called the Winter Pearmain: this is a good sized fruit, rather long than round, of a fine red next the sun, and striped with the same colour on the other side; the flesh is juicy, and stews well, but is not esteemed for eating by any nice palates. This is fit for use in November and December.

The Kentish Pippin is a large handsome fruit, of an oblong figure; the skin is of a pale green colour; the flesh is breaking, and full of juice, which is of a quick acid flavour. This is a very good kitchen fruit, and will keep till February.

The Holland Pippin is larger than the former; the fruit is somewhat longer, the skin of a darker green,

M A L

and the flesh firm and juicy. This is a very good kitchen fruit, and will keep late in the season.

The Monstrous Renette is a very large Apple, of an oblong shape, turning red toward the sun, but of a dark green on the other side; the flesh is apt to be mealy, so it is not much valued by those who are curious, and only preserved for the magnitude of the fruit.

The Embroidered Apple is a pretty large fruit, somewhat shaped like the Pearmain, but the stripes of red are very broad, from whence the gardeners have given it this title: it is a middling fruit, and is commonly used as a kitchen Apple, though there are many better.

The Royal Russet, by some called the Leather Coat Russet, on account of the deep russet colour of the skin; this is a large fair fruit, of an oblong figure, broad toward the base; the flesh is inclinable to yellow. This is one of the best kitchen Apples we have, and is a very great bearer: the trees grow large and handsome, and the fruit is in use from October till April, and is also a pleasant fruit to eat.

Wheeler's Russet is an Apple of a middling size, flat, and round; the stalk is slender, the side next the sun of a light russet colour, and the other side inclining to a pale yellow, when ripe; the flesh is firm, and the juice has a very quick acid flavour, but is an excellent kitchen fruit, and will keep a long time.

Pile's Russet is not quite so large as the former, but is of an oval figure, of a russet colour to the sun, and of a dark green on the other side; it is a very firm fruit, of a sharp acid flavour, but is much esteemed for baking, and will keep sound till April, or later, if they are well preserved.

The Nonpareil is a fruit pretty generally known in England, though there is another Apple which is frequently sold in the markets for it, which is what the French call Haute-bonne; this is a larger fairer fruit than the Nonpareil, more inclining to the yellow; the russet colour brighter, and it is earlier ripe, and sooner gone; this is not so flat as the true Nonpareil, nor is the juice so sharp, though it is a good Apple in its season; but the Nonpareil is seldom ripe before Christmas, and where they are well preserved they will keep till May perfectly sound; this is justly esteemed one of the best Apples that have been yet known.

The Golden Pippin is a fruit almost peculiar to England; there are few countries abroad where this succeeds well, nor do they produce so good fruit in many parts of England as were to be wished; which, in some measure, is owing to their being grafted on free stocks, which enlarges the fruit, but renders it less valuable, because the flesh is not so firm, nor the flavour so quick, so is apt to be dry and mealy; therefore this should always be grafted upon the Crab stock, which will not canker like the others, and though the fruit will not be so fair to the sight, yet it will be better flavoured and keep longer.

There are yet a great variety of Apples, which, being inferior to those here mentioned, I have omitted, as those which are here enumerated will be sufficient to furnish the table and the kitchen, during the whole season of these fruits; so that where these sorts can be had, no person of taste will eat the other. I shall here mention some of the Apples which are chiefly preferred for the making of cyder, tho' there are in every cyder country, new sorts frequently obtained from the kernels; but those hereafter mentioned, have, for some years, been in the greatest esteem.

The Red-streak.

Devonshire Royal Wilding.

The Whitsour.

John Apple, or Deux-annes.

Everlasting Hanger.

Gennet Moyle.

All the sorts of Apples are propagated by grafting or budding upon the stocks of the same kind, for they will

will not take upon any other sort of fruit tree. In the nurseries there are three sort of stocks generally used to graft Apples upon; the first are called free stocks; these are raised from the kernels of all sorts of Apples indifferently, and sometimes they are also termed Crab stocks; for all those trees which are produced from the seeds before they are grafted, are termed Crabs without any distinction; but, as I have before observed, I should always prefer such stocks as are raised from the kernels of Crabs, where they are pressed for verjuice; and I find several of the old writers on this subject of the same mind. Mr. Austen, who wrote above a hundred years ago, says, "The stock which he accounts best for Apple grafts is the Crab, which is better than sweeter Apple-trees to graft on, because they are usually free from canker, and will become very large trees; and, I conceive, will last longer than stocks of sweeter Apples, and will make fruits more strong and hardy to endure frost;" and it is very certain, that by frequently grafting some sorts of Apples upon free stocks, the fruits have been rendered less firm and poignant, and of shorter duration.

The second sort of stock is the Dutch Creeper, before-mentioned; these are designed to stint the growth of the trees, and keep them within compass for dwarfs or espaliers.

The third sort is the Paradise Apple, which is a very low shrub, so only proper for trees which are kept in pots, by way of curiosity, for these do not continue long.

Some persons have made use of Codlin stocks for grafting of Apples, in order to stint their growth; but as these are commonly propagated by suckers, I would by no means advise the using of them; nor would I chuse to raise the Codlin-trees from suckers, but rather graft them upon Crab stocks, which will cause the fruit to be firmer, last longer, and have a sharper flavour; and these trees will last much longer sound, and never put out suckers, as the Codlins always do, which, if not constantly taken off, will weaken the trees, and cause them to canker: and it is not only from the roots, but from the knots of their stems, there are generally a great number of strong shoots produced, which fill the trees with useless shoots, and render them unsightly, and the fruit small and crumpled.

The method of raising stocks from the kernels of Crabs, or Apples, is, to procure them where they are pressed for verjuice or cyder, and after they are cleared of the pulp, they may be sown upon a bed of light earth, covering them over about half an inch thick with the same light earth; these may be sown in November or December, where the ground is dry, but in wet ground, it will be better to defer it till February; but then the seeds should be preserved in dry sand, and kept out of the reach of vermin, for if mice or rats can get at them, they will devour the seeds; there should also be care taken of the seeds, when they are sown, to protect them from these vermin, by setting traps to take them, &c. In the spring, when the plants begin to appear, they must be carefully weeded, and if the season should prove dry, it will be of great service to water them two or three times a week; and, during the summer, they must be kept clean from weeds, which, if suffered to grow, will soon over-top the plants, and spoil their growth; if these thrive well, they will be fit to transplant into the nursery the October following, at which time the ground should be carefully digged, and cleansed from the roots of all bad weeds; then the stocks should be

planted in rows three feet asunder, and the plants one foot distance in the rows, closing the earth pretty fast to their roots; when the stocks are transplanted out of the seed-bed, the first autumn after sowing, they need not be headed, but where they are inclined to shoot downward, the tap root must be shortened, in order to force out horizontal roots; if the ground is pretty good in which these stocks are planted, and the weeds constantly cleared away, the stocks will make great progress, so that those which are intended for dwarfs, may be grafted the spring twelve months after they are planted out of the seed-bed; but those which are designed for standards will require two or three years more growth, before they will be fit to graft, by which time they will be upward of six feet high. The other necessary work to be observed in the culture of these trees, while they remain in the nursery, being exhibited under the article of NURSERY, I shall not repeat in this place.

I shall next treat of the manner of planting such of these trees, as are designed for espaliers in the kitchen-garden, where, if there is an extent of ground, it will be proper to plant, not only such sorts as are for the use of the table, but also a quantity of trees to supply the kitchen; but where the kitchen-garden is small, the latter must be supplied from standard-trees, either from the orchard, or wherever they are planted; but as many of these kitchen Apples are large, and hang late in the autumn upon the trees, they will be much more exposed to the strong winds on standard trees than in espaliers, whereby many of the fruit will be blown down before they are ripe, and others bruised, so as to prevent their keeping; therefore where it can be done, I should always prefer the planting them in espaliers.

The distance which I should chuse to allow these trees, should not be less than thirty feet, for such sorts as are of moderate growth (if upon Crab or free stocks:) but the larger growing sorts should not be allowed less room than thirty-five or forty feet, which will be found full near enough, if the ground is good, and the trees properly trained; for as the branches of these trees should not be shortened, but trained at their full length, so in a few years they will be found to meet. Indeed, at the first planting, the distance will appear so great to those persons who have not observed the vigorous growth of these trees, that they will suppose they never can extend their branches so far, as to cover the espalier; but if these persons will but observe the growth of standard-trees of the same kinds, and see how wide their branches are extended on every side, they may be soon convinced, that as these espalier-trees are allowed to spread but on two sides, they will of course make more progress, as the whole nourishment of the root will be employed in these side branches, than where there is a greater number of branches on every side of the tree, which are to be supplied with the same nourishment.

The next thing to be observed is the making choice of such sorts of fruits as grow nearly alike, to plant in the same espalier. This is of great consequence, because of the distance they are to be placed, otherwise those sorts which make the largest shoots, may be allowed less room to spread than those of smaller growth; beside, when all the trees in one espalier are nearly equal in growth, they will have a better appearance than when some are tall, and others short; but for the better instruction of those persons who are not conversant in these things, I shall divide the sorts of Apples into three classes according to their different growths.

M A L

Largest growing tree.

All the sorts of Pearmain.
Kentish Pippin.
Holland Pippin.
Monstrous Renette.
Royal Russet.
Wheeler's Russet.
Pile's Russet.
Nonpareil.
Violet Apple.

Middle growing tree.

Margaret Apple.
Golden Renette.
Aromatic Pippin.
Embroidered Apple.
Renette Grise.
White Renette.
Codlin.

M A L

Smallest growing tree.

Quince Apple.
Transparent Apple.
Golden Pippin.
Pomme d'Api.
Fenouillet, or Anis Apple.

N. B. These are all supposed to be grafted on the same sort of stocks.

If these Apples are grafted upon Crab stocks, I would willingly place them at the following distance from each other, especially where the soil is good, viz. the largest growing trees at forty feet, the middle growing at thirty feet, and the small growing at twenty-five feet, which, from constant experience, I find to be full near enough; for in many places, where I have planted these trees at twenty-four feet distance, they have shot so strong, as that in seven years their branches have met; and in some places where every other tree hath been taken up, the branches have almost joined in seven years after; therefore it will be much the better way to plant these trees at a proper distance at first, and between these to plant some Dwarf Cherries, Currants, or other sorts of fruit, to bear for a few years, which may be cut away when the Apple-trees have extended their branches to them; for when the Apple-trees are planted nearer together, few persons care to cut down the trees, when they are fruitful, so that they are obliged to use the knife, saw, and chisel, more than is proper for the future good of the trees; and many times, where persons are inclinable to take away part of their trees, the distances will be often so irregular (where there was not this consideration in their first planting,) as to render the espalier unsightly.

When the trees are upon the Dutch Dwarf stock, the distance should be for the larger growing trees thirty feet, for those of middle growth twenty-five, and the smallest twenty feet, which will be found full near where the trees thrive well.

The next is the choice of the trees, which should not be more than two years growth from the graft, but those of one year should be preferred; you should also be careful, that their stocks are young, sound, and smooth, free from canker, and which have not been cut down once or twice in the nursery; when they are taken up, all the small fibres should be entirely cut off from their roots, which, if left on, will turn mouldy and decay, so will obstruct the new fibres, which will soon push out, in their growth; the extreme part of the roots must also be shortened, and all bruised roots cut off; and if there are any misplaced roots which cross each other, they should also be cut away. As to the pruning of the head of these trees, there need be nothing more done than to cut off any branches which are so situated, as that they cannot be trained to the line of the espalier: in the planting, there must be care taken not to place their roots too deep in the ground, especially if the soil is moist, but rather raise them on a little hill, which will be necessary to allow for the raising of the borders afterward. The best season for planting these trees (in all soils which are not very moist) is, from October, to the middle or latter end of November, according as the season continues mild; but so soon as the leaves fall, they may be removed with great safety. After the trees are planted, it will be proper to place down a stake to each tree, to which the branches should be fastened, to prevent the winds from shaking or loosening their roots, which will destroy the young fibres; for when these trees are planted pretty early in autumn, they will very soon push out a great number of new fibres, which, being very tender, are soon broken, by the wind shaking

of the trees, whereby they are greatly injured. If the winter should prove severe, it will be proper to lay some rotten dung, tanners bark, or some other sort of mulch about their roots, to prevent the frost from penetrating of the ground, which might damage these tender fibres; but I would not advise the laying of this mulch before the frost begins, for if it is laid over the surface of the ground about their roots, soon after the trees are planted (as is often practised,) it will prevent the moisture entering the ground, and do much more harm than good to the trees.

The following spring, before the trees begin to push, there should be two or three short stakes put down on each side every tree, to which the branches should be fastened down as horizontally as possible, never cutting them down, as is by some practised, for there will be no danger of their putting out branches enough to furnish the espalier, if the trees are once well established in their new quarters.

In the pruning of these trees, the chief point is, never to shorten any of the branches, unless there is an absolute want of shoots to fill the spaces of the espalier; for where the knife is much used, it only multiplies useless shoots, and prevents their fruiting; so that the best method to manage these trees is, to go over them three or four times in the growing season, and rub off all such shoots as are irregularly produced, and train the others down to the stakes in the position they are to remain: if this is carefully performed in summer, there will be little left to be done in the winter, and by bending of their shoots from time to time, as they are produced, there will be no occasion to use force to bring them down, nor any danger of breaking the branches. The distance which these branches should be trained from each other, for the largest sorts of fruits should be about seven or eight inches, and for the smaller four or five. If these plain instructions are followed, it will save much unnecessary labour of pruning, and the trees will, at all times, make a handsome appearance; whereas when they are suffered to grow rude in summer, there will be much greater difficulty to bring down their shoots, especially if they are grown stubborn, when it may become necessary to slit the branches to make them pliable. All the sorts of Apples produce their fruit upon cusions, or spurs, so that these should never be cut off, for they will continue fruitful a great number of years.

The method of making the espaliers having been already exhibited under that article, I need not repeat it here, but only observe, that it will be best to defer making the espalier till the trees have had three or four years growth; for before that time, the branches may be supported by a few upright stakes, so that there will be no necessity to make the espalier, until there are sufficient branches to furnish all the lower part.

I shall now treat of the method to plant orchards, so as to have them produce the greatest profit. And first, in the choice of the soil and situation for an orchard: the best situation for an orchard is, on the ascent of the gentle hills, facing the south, or south-east; but this ascent must not be too steep, lest the earth should be washed down by hasty rains. There

are many persons who prefer low situations at the foot of hills, but I am thoroughly convinced from experience, that all bottoms where there are hills on each side, are very improper for this purpose; for the air is drawn down into these vallies in strong currents, which, being pent in renders these bottoms much colder than the open situations; and during the winter and spring, these bottoms are very damp and unhealthy to all vegetables; therefore the gentle rise of a hill, fully exposed to the sun and air, is by much the best situation. As to the soil, a gentle hazel loam, which is easy to work, and that doth not detain the wet, is the best; if this happens to be three feet deep, it will be better for the growth of the trees, for although these trees will grow upon very strong land, yet they are seldom so thriving, nor are their fruit so well flavoured, as those which grow on a gentle soil; and on the other hand, these trees will not do well upon a very dry gravel or sand, therefore those soils should never be made choice of for orchards.

The ground intended to be planted should be well prepared the year before, by ploughing it thoroughly, and if some dung is laid upon it the year before, it will be of great service to the trees; if in the preceding spring a crop of Peas or Beans is planted on the ground (provided they are sown or planted in rows, at a proper distance, so as that the ground between them is horse-hoed,) it will destroy the weeds, and loosen the ground, so that it will be a good preparation for the trees, for the earth cannot be too much wrought, or pulverised for this purpose: these crops will be taken off the ground long before the season for planting of these trees, which should be as soon as possible performed when the trees begin to shed their leaves.

In chusing of the trees, I would advise the taking such as are but of two years growth from the graft, and never to plant old trees, or such as are grafted upon old stocks, for it is losing of time to plant these; young trees being always more certain to grow, and make a much greater progress than those which are old. As to pruning of the roots, it must be done in the same manner as hath been already directed for the espalier-trees; and in pruning their heads, little more is necessary than to cut out such branches as are ill placed, or that cross each other; for I do not approve the heading of them down, as is by some often practised to the loss of many of their trees.

The distance which these trees should be planted, where the soil is good, must be fifty or sixty feet; and where the soil is not so good, forty feet may be sufficient; but nothing can be of worse consequence, than the crowding trees too close together in orchards. And although there may be some who may imagine this distance too great, yet I am sure, when they have thoroughly considered the advantages attending this practice, they will agree with me. Nor is it my own opinion in this affair, for in many of the old writers on this subject, there is often mention made of the necessity for allowing a proper distance to the fruit-trees in orchards, particularly Austen, upon planting before quoted, who says, "He should chuse to prescribe the planting these trees fourteen or sixteen yards asunder; for both trees and fruits have many great advantages, if planted a good distance one from another." One advantage he mentions is, "The sun refreshes every tree, the roots, body, and branches, with the blossoms and fruits; whereby trees bring forth more fruit, and those fairer and better." Another advantage he mentions is, "That when trees are planted at a large distance, much profit may be made of the ground under and about these trees, by cultivating garden-stuff, commodious as well for sale as housekeeping; as also Gooseberries, Raspberries, Currants, and Strawberries, may be there planted." Again he says, "When trees have room to spread, they will grow very large and great; and the consequences of that will be, not only multitudes of fruits, but also

"long lasting, and these two are no small advantages." For, says he, "Men are mistaken, when they say, the more trees in an orchard, the more fruits; for one or two large trees which have room to spread, will bear more fruits than six or ten (it may be) of those that grow near together, and crowd one another." Again he says, "Let men but observe, and take notice of some Apple-trees, that grow a great distance from other trees, and have room enough to spread both their roots and branches, and they shall see, that one of those trees (being come to full growth) hath a larger head, and more boughs and branches, than (it may be) four, or six, or more, of those which grow near together, although of the same age."

And Mr. Lawson, an ancient planter, advises to plant Apple-trees twenty yards asunder. As the two authors above quoted have written the best upon this subject, and seem to have had more experience than any of the writers I have yet seen, I have made use of them as authorities to confirm what I have advanced; though the fact is so obvious to every person who will make the least reflection, that there needs no other proof.

When the trees are planted, they should be staked, to prevent their being shaken, or blown out of the ground by strong winds; but in doing of this, there should be particular care taken, to put either straw, haybands, or woollen cloth, between the trees and the stakes, to prevent the trees from being rubbed and bruised, by the shaking against the stakes, for if their bark should be rubbed off, it will occasion such great wounds, as not to be healed over in several years, if they ever recover it.

If the winter should prove very severe, it will be proper to cover the surface of the ground about their roots with some mulch, to prevent the frost from penetrating the ground, which will destroy the young fibres; but this mulch should not be laid on too soon, as hath been before mentioned, lest the moisture should be prevented from soaking down to the roots of the trees, nor should it lie on too long in the spring for the same reason; therefore where persons will be at the trouble to lay it on in frosty weather, and remove it again after the frost is over, that the wet in February may have free access to the roots of the trees; and if March should prove dry, with sharp north or east winds, which often happens, it will be proper to cover the ground again with the mulch, to prevent the winds from penetrating and drying the ground, and will be of singular service to the trees. But I am aware, that this will be objected to by many, on account of the trouble, which may appear to be great; but when it is considered, how much of this business may be done by a single person in a short time, it can have little force, and the benefit which the trees will receive by this management, will greatly recompense the trouble and expence.

As these trees must be constantly fenced from cattle, it will be the best way to keep the land in tillage for some years, that by constant ploughing or digging of the ground, the roots of the trees will be more encouraged, and they will make the more progress in their growth; but where this is done, whatever crops are sown or planted, should not be too near the trees, lest the nourishment should be drawn away from the trees; and as in the ploughing of the ground where it is so tilled, there must be care taken not to go too near the stem of the trees, whereby their roots would be injured, or the bark of their stems rubbed off, so it will be of great service to dig the ground about the trees where the plough doth not come, every autumn, for five or six years after planting, by which time their roots will have extended themselves to a greater distance.

It is a common practice in many parts of England, to lay the ground down for pasture, after the trees are grown pretty large in their orchards; but this is by no means advisable, for I have frequently seen trees of above twenty years growth, almost destroyed by horses,

M A M

horses, in the compass of one week; and if sheep are put into orchards, they will constantly rub their bodies against the stems of the trees, and their grease sticking to the bark, will stint their growth, and in time will spoil them; therefore wherever orchards are planted, it will be much the better method to keep the ground ploughed or dug annually, and such crops put on the ground as will not draw too much nourishment from the trees.

In pruning of orchard-trees, nothing more should be done, but to cut out all those branches which cross each other, and, if left, would rub and tear off the bark, as also decayed branches, but never shorten any of their shoots. If suckers, or shoots from their stems, should come out, they must be entirely taken off annually; and when any branches are broken by the wind, they should be cut off, either down to the division of the branch, or close to the stem from whence it was produced; the best time for this work is in November, for it should not be done in frosty weather, nor in the spring, when the sap begins to be in motion.

The best method to keep Apples for winter use is, to let them hang upon the trees until there is danger of frost, and to gather them in dry weather, laying them in large heaps to sweat for three weeks or a month; afterward look them over carefully, taking out all such as have appearance of decay, wiping all the sound fruit dry, and pack them up in large oil-jars, which have been thoroughly scalded and dry, stopping them down close to exclude the external air: if this is duly observed, the fruit will keep sound a long time, and their flesh will be plump; for when they are exposed to the air, their skins will shrink, and their pulp will be soft.

MAMMEA. Plum. Nov. Gen. 44. tab. 4. Lin. Gen. Plant. 583. The Mammee-tree.

The **CHARACTERS** are,

The empalement of the flower is composed of two small, oval, concave leaves, which fall off. The flower has four large concave petals, which spread open. It hath many awl-shaped stamina, terminated by roundish summits, and in the center a roundish germen, with a conical style the length of the stamina, crowned by a single permanent stigma. The germen afterward turns to a large fleshy fruit, of a spherical figure, inclosing one, two, or three large almost oval stones.

This genus of plants is ranged in the first section of Linnæus's thirteenth class, intitled Polyandria Monogynia, which includes the plants whose flowers have many stamina and one style.

There is but one **SPECIES** of this tree known in the English gardens, viz.

MAMMEA *staminibus flore brevioribus. Mammee with the stamina shorter than the flower. Mammea magno fructu, pericæ sapore.* Plum. Nov. Gen. 44. *Mammee with a large fruit, having the taste of a Peach.*

This tree, in the West-Indies, grows to the height of sixty or seventy feet; the leaves are large and stiff, and continue green all the year; the fruit is as large as a man's fist; when ripe, it is of a yellowish green colour, and is very grateful to the taste. It grows in great plenty in the Spanish West-Indies, where the fruit is generally sold in their markets, and is esteemed one of the best fruits in the country. It also grows on the hills of Jamaica, and has been transplanted into most of the Caribbee Islands, where it thrives exceeding well.

In England there are some few of these plants, which are preserved with great care by such as are curious in cultivating exotic plants; but there are none of any considerable size, so that we cannot expect to see either fruit or flowers for some years. These plants may be propagated by planting the stones, which are

M A N

often brought from the West-Indies, (which should be very fresh, otherwise they will not grow,) into pots filled with fresh light earth, and plunged into a hot-bed of tanners bark, observing to water the earth whenever it appears dry. In about a month or six weeks the plants will appear above ground, after which they must be frequently refreshed with water; and in hot weather the glasses of the hot-bed should be raised to let in fresh air. In two months the roots of the plants will have filled the pots, when you should provide some pots of a little larger size, into which you should transplant the plants, being careful to preserve as much earth to their roots as possible; then you should fill up the pots with fresh light earth, and plunge them into the bark-bed again, observing to water and shade them until they have taken root, after which they should be constantly refreshed with water as you shall find they want it, and must have air in hot weather. In this bed they may remain till Michaelmas, when they must be removed into the bark-stove, where they must be constantly kept, observing to refresh them with water, but it must be given to them sparingly at this season, as also to clean their leaves from the filth they are apt to contract in the stove; the spring following they should be shifted into fresh earth, and if they require it, into larger pots, but by no means over-pot them, for they do not produce many roots, therefore if the pots are too large the plants will not thrive; they must be constantly kept in the bark-stove, and may be treated after the manner directed for the Coffee-tree.

If, when the stones of this fruit are brought over, they are put into the tan-bed, under the bottom of any of the pots, they will sprout sooner than those which are planted in the earth.

MANCANILLA. See **HIPPOMANE**.

MANDRAGORA. Tourn. Inst. R. H. 76. tab. 12. Lin. Sp. Plant. 221. Mandrake; in French, *Mandragore*.

The **CHARACTERS** are,

The empalement of the flower is large, bell-shaped, erect, and permanent; it is of one leaf, cut at the top into five acute segments. The flower hath one erect bell-shaped petal which spreads open, and is a little larger than the empalement. It has five awl-shaped stamina, which are arched and hairy at their base. In the center is situated a roundish germen, supporting an awl-shaped style, crowned by a beaded stigma. The germen afterward turns to a large round berry with two cells, having a fleshy receptacle convex on each side, filled with kidney-shaped seeds.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, which contains those plants whose flowers have five stamina and one style.

We have but one **SPECIES** of this genus in the English gardens, viz.

MANDRAGORA (*Officinatum*.) Hort. Cliff. 51. *The Mandrake. Mandragora fructu rotundo.* C. B. P. 169. *Mandrake with a round fruit.*

This plant grows naturally in Spain, Portugal, Italy, and the Levant, but is preserved here in the gardens of the curious. It hath a long taper root shaped like Parsnep, which runs three or four feet deep in the ground; it is sometimes single, and at others divided into two or three branches, almost of the colour of Parsnep, but a little darker; from this arises a circle of leaves, which at first stand erect, but, when grown to their full size, spread open, and lie upon the ground; they are more than a foot in length, and four or five inches broad in the middle, growing narrow toward both ends, of a dark green colour, and a foetid scent. These rise immediately from the crown of the root, without any foot-stalk; between them come out the flowers, each standing upon a separate foot-stalk about three inches long, which also arise immediately from the root; they are five-cornered, of an herbaceous white colour, spreading open at the top like a Primrose, having five hairy stamina, with a globular germen in the center, supporting an awl-shaped style. The germen afterward turns to a globular

M A N

bular soft berry lying upon the leaves, which, when fully grown, is as large as a Nutmeg, of a yellowish green colour when ripe, full of pulp, in which the kidney-shaped seeds are lodged. It flowers in March, and the seeds are ripe in July.

This plant is propagated by seeds, which should be sown upon a bed of light earth soon after they are ripe, for if they are kept until the spring, they seldom succeed well; but those which are sown in autumn will come up in the spring, when they should be carefully cleared from weeds; and in very dry weather they must be refreshed with water, which will greatly promote their growth. In this bed they should remain till the latter end of August, (observing always to keep them clear from weeds) at which time they should be taken up very carefully, and transplanted into the places where they are to remain; the soil should be light and deep, for their roots always run very deep, so that if the soil is wet, they are often rotted in winter; and if it be too near the gravel or chalk, they will make but little progress; but if the soil be good and they are not disturbed, the plants will grow to a large size in a few years, and will produce great quantities of flowers and fruit; the roots will abide a great many years.

I have been informed by some persons of credit, that one of these roots will remain sound above fifty years, and be as vigorous as a young plant. I have known some plants myself near that age, which are now in great vigour, and may continue so many years longer, as there are no signs of their decay; but they should never be removed after their roots have arrived to any considerable size, which would break their lower fibres, and so flint the plants, as that if they live they will not recover their former strength in two or three years. These plants should have a warm situation, otherwise in severe winters they will be destroyed.

As to the feigned resemblance of a human form, which the roots of this plant are said to carry, it is all imposture, owing to the cunning of quacks and mountebanks, who deceive the populace and the ignorant with fictitious images, shaped from the fresh roots of Briony and other plants: and what is reported as to the manner of rooting of this plant, by tying a dog thereto, to prevent the certain death of the person who should care to attempt it, and the groans it emits upon the force offered, &c. is all a ridiculous fable; for I have taken up several large roots of this plant, some of which have been transplanted into other places, but could never observe any particular difference in this from any other deep rooting plant.

MANGIFERA. Lin. Gen. Plant. 278. The Mango-tree.

The CHARACTERS are,

The empalement of the flower is cut into five spear-shaped segments; the flower hath five spear-shaped petals longer than the empalement, and five awl-shaped stamina the length of the corolla, crowned with heart-shaped summits. It hath a roundish germen, supporting a slender style the length of the empalement, terminated by a single stigma; the germen afterward becomes an oblong kidney-shaped Plumb somewhat compressed, inclosing an oblong woolly nut of the same form.

This genus of plants is ranged in the first section of Linnæus's fifth class, intitled Pentandria Monogynia, the flower having five stamina and one style.

We have but one SPECIES of this genus, viz.

MANGIFERA (Indica.) Lin. Sp. 290. *The Mango-tree.* Manga Indica fructu magno reniforma. Raii Hist. 1550.

This tree grows naturally in most parts of India, as also in the Brazils, and some other parts of the world, where it becomes a large tree; the wood is brittle, and the bark becomes rough by age; the leaves are seven or eight inches long, and two or more broad, terminating in points, having several transverse veins from the middle rib to the sides, which are opposite. The flowers are produced in loose panicles toward the end of the branches, each consisting of five spear-

M A N

shaped petals which spread open, having five awl-shaped stamina the length of the petals, which are situated between them; the germen at the bottom of the flower afterward becomes a large oblong kidney-shaped Plumb, inclosing a rough nut of the same form.

This fruit, when fully ripe, is greatly esteemed by the inhabitants of those countries where they grow naturally, or have been transplanted; but in Europe we have only the unripe fruit brought over in pickle, which is little better than several other fruit when pickled in the same way: however, from the account given of the ripe fruit, by most people who have eaten it in the country; it has excited the curiosity of many persons in Europe to endeavour to procure young plants in their gardens, for which purpose great quantities of the nuts have been brought to several parts of Europe, but without effect; for I have not heard of one plant which has been produced in Europe from the nuts. All those which have fallen into my hands have been rotten when received, so that I am apt to think the vegetative quality of them cannot be long preserved; therefore the only method to obtain the plants in England, is to plant a good quantity of the nuts in a tub of earth in the country where they grow naturally; and when the plants are grown a foot high, to ship them for England, placing a covering over them to defend them from salt water and the spray of the sea, being very careful not to let them have much wet in their passage; as also when the ship arrives in a cold climate, to screen the plants from cold, especially if it is toward the approach of winter. By carefully observing these rules, the plants may be brought very safely over, as has been experienced by a plant of this sort, with several other sorts of plants, which were brought over by Capt. Quick, and are now in good health in the Chelsea garden.

There have been some plants brought to England before this, which were destroyed by having too much heat, for this plant will not thrive in a hot-bed of tanners bark; so that the only way to have them succeed, is to plant them in pots filled with light kitchen-garden earth, and place them in a dry stove, where in warm weather they should have fresh air daily, and in the winter the air kept up to temperate, as is marked upon the thermometers.

MANIHOT. See JATROPHA.

MANURE.

There are various kinds of Manure, which are now commonly used in different parts of England, for enriching of the several soils. Some of these have been already mentioned under the article of DUNG, so I shall not repeat them here, but proceed to take notice of some other kinds of Manure, which are at present neglected by many people, though they might be used with equal success, if not better on many lands, as most of those now commonly in use.

Oak bark, after the tanners have used it for tanning of leather, when laid in a heap and rotted, is an excellent Manure, especially for stiff cold land; in which one load of this Manure will improve the ground more, and last longer, than two loads of the richest dungs; and yet it is very common to see large heaps of this remaining in the tanners yards for many years, in several parts of England, where Manure of other kinds is very scarce, and often carried to a great distance. Of late years this tan has been much used for hot-beds in several parts of England, and is found greatly to exceed horse dung for that purpose, the fermentation being moderate and of long continuance; so that a bed of tan, when rightly made, will continue in a moderate temperature of heat for three or four months; and when the heat begins to decay, if it be stirred up with a dung fork, and some fresh tan added to it, the heat will renew again, and last for some months, so that these beds are by far the most kindly for exotic plants; and whatever plants are plunged into these beds, if they are permitted to root through the bottom of the pots, they will thrive more in one month after, than they did in four months while they

they are confined to the pots. I have frequently observed many kinds of plants, which were rooted through the pot into the tan, and have sent forth roots upward of twelve feet each way, in less than three months, and the plants have advanced in proportion; which is a plain indication, that plants are greatly nourished by the rotten tan. After the tan hath been used for a hot-bed, I have spread it on the ground for Manure, and found it has greatly enriched the ground; but it is much better for cold strong land, than for light hot ground, because it is of a warm nature, and will loosen and separate the earth; so that where this Manure hath been used three or four times, it hath made the land very loose which before was strong, and not easy to be wrought. When this Manure is laid upon Grass, it should be done soon after Michaelmas, that the winter rains may wash it into the ground; for if it is laid on in the spring, it will burn the Grass, and instead of improving it, will greatly injure it for that season. Where it is used in Corn land, it should be spread on the surface before the last ploughing, that it may be turned down for the fibres of the Corn to reach it in the spring; for if it lies too near the surface, it will forward the growth of the Corn in winter: but in the spring, when the nourishment is chiefly wanted to encourage the stems, it will be nearly consumed, and the Corn will receive little advantage from it. Nor will it be proper to have this Manure lie too near the roots of any plants, for when this has happened, I have frequently observed it prejudicial to most plants, but especially to bulbous and tuberosc-rooted flowers, which are very subject to rot where it lies near their roots; yet when it is buried just deep enough for the fibres of their roots to reach it in the spring, the flowers have been exceedingly improved by it. And in some places, where this Manure hath been used in kitchen-gardens, it hath greatly improved the vegetables; so that it is to be wondered, that this should not be employed on the land in every country where it can be obtained.

Rotten vegetables of most sorts also will enrich land, so that where other Manure is scarce, these may be used with success. The weeds of ponds, lakes, or ditches, being dragged out before they seed, and laid in heaps to rot, will make good Manure, as will most other sorts of weeds; but wherever any of these are employed, they should be cut down as soon as they begin to flower, for if they are suffered to stand until their seeds are ripe, the land will be stored with weeds, which cannot be easily destroyed; nay, some kinds of weeds, if they are permitted to stand so long as to form their seed, will perfect them after they are cut down, which may be equally prejudicial to the land: therefore the surest method is, to cut them down just as they begin to flower; at which time most sorts of vegetables are in their greatest vigour, being then stronger and fuller of juice, than when their seeds are farther advanced; so that at that time they abound most with salts, and therefore are more proper for the intended purpose. In rotting of these vegetables, it will be proper to mix some earth, mud, or any other such like substance with them, to prevent their taking fire in their fermentation; which they are very subject to, where they are laid in large heaps without any other mixture to prevent it; and it will be also proper to cover the heaps over with earth, mud, or dung, to detain the salts, otherwise many of the finer particles will evaporate in fermenting. When these vegetables are thoroughly rotted, they will form a solid mass, which will cut like butter, and be very full of oil, which will greatly improve land.

In such places where there are neither ponds, lakes, or ditches, to supply these weeds, and the situation being far from the sea (from whence also may be obtained many sorts of weeds for this purpose) there may be many sorts of vegetables sown, in order to plough them into the grounds when they are full grown, to enrich the land; at present those chiefly

used for this purpose are Buck Wheat, Vetches, and Spurry. And in some countries abroad they commonly sow Lupines upon such land as they want to improve, and when they are full grown they mow them down, and plough them into the ground, which they esteem to be good Manure. This is chiefly used in the south of France and in Italy, where some of the sorts of Lupines grow naturally; but these are not proper for this climate; because, if the season should prove cold or wet after the Lupines are sown, they will rot in the ground, so that it is very hazardous to sow them in this country; and there being many other sorts of plants which are hardy, and grow to a much larger size with us than Lupines, they should be preferred to them for this purpose. I have known some land sown pretty thick with Horse-beans which have been mowed down when they were in blossom, and ploughed in for a crop of Wheat, and it hath largely repaid the owner. Almost any of the pulse kind, which grow large, are very proper to be sown for this purpose; and next to these may be sown Mustard, Cole-seed, or any of these large growing plants; which, if cut before they form their seeds, and ploughed in, will greatly enrich the ground.

The refuse of kitchen-gardens, when laid in heaps and rotted, will also afford a good sort of Manure for Corn land; but as this is not to be obtained in any quantity, excepting near great cities, so, in such places, dung being to be had pretty reasonable, the other will not be much sought after.

I have lately been informed of another improvement, which may be of great use in several parts of the kingdom; which is, the mowing down of Fern while it is green and tender, and laying it in heaps to rot, which will make a tolerable Manure for land; and as this is a most troublesome plant in many parts of England, so by frequently mowing, it may be destroyed; and when rotted, a good quantity of this Manure may be obtained, which will more than defray the charges of cutting it down. In some places, where no tan or horse-dung can be obtained, they have cut down Fern and chopped it pretty small, and laid it in a heap to ferment, then have used it for hot-beds, for which purpose it has answered pretty well. The first person who informed me of this, was Mr. Samuel Brewer, a very curious gentleman in gardening, who made several hot-beds of Fern, which, he says, continued their heat for some months; so that he prefers it to dung, where a moderate lasting heat is required.

There are many kinds of weeds which infest the lands in many parts of England, which, if cut down at a proper time and laid to rot, might be used to great advantage for manuring of land; and hereby the weeds may in time be destroyed, and the Manure would more than pay the expence of doing it: but few persons who are employed in husbandry care to go out of their old beaten road to try experiments, even where they are attended with little expence and nothing hazarded; otherwise there is great room to make improvements of this kind, especially in countries where dung, or other common Manure is very scarce; in which places, if some experiments were properly made, of rotting whatever vegetables could be procured in the neighbourhood, it might turn to good account.

The ashes of all kinds of vegetables are an excellent Manure for land, so that where the ground is overrun with bushes, brambles, &c. which are become woody, if they are grubbed up in summer, and spread abroad to dry for a little time, then gently consumed to ashes, and these spread on the land, it will greatly improve it. The method for doing this is already explained under the article of LAND.

Rotten wood, and saw-dust when rotted, is a very good Manure for strong land, because it loosens the parts of the earth and renders it light.

Bones, horns, and other parts of animals, also enrich land greatly, as do decayed fish; so that in some

M A R

places where these can be easily obtained, a great improvement may be made of them.

Sea-sand and shells are in several parts of England used to great advantage, especially in Devonshire, where they are at the expence of fetching the sand and shells on horses backs, twelve or fourteen miles. The land on which they lay this Manure, is a strong loam inclining to clay; so that this separates the parts, and the salts which are contained in the dressing are a very great improvement of their land. Coral, and such kinds of stony plants which grow on the rocks, are filled with salts which are very beneficial to land; but as these bodies are hard, the improvement is not the first or second year after they are laid on the ground, because they require time to pulverize them before their salts can mix with the earth to impregnate it. Therefore dressings of this kind are seldom used by tenants, who want to reap the fruit of their labour as soon as possible. But these Manures are much better for cold strong land, than for that which is light and sandy. In some countries, at a great distance from the sea, have been discovered great quantities of fossil shells, which have been dug out of the earth, and used as Manure, which have improved the ground a little, especially strong land: as these have little salts, when compared to those shells which are taken from the shore, therefore where the latter can be obtained, they other are scarce worth using.

Where the land lies near the sea, so that either sand, shells, corals, wrecks, or sea-weeds, can be obtained at an easy expence, they are by far the best kinds of Manure, because they enrich the land for several years; for as their salts are closely locked up, they are communicated by degrees to the land, as the heat and cold causes the bodies to pulverize, and fall into small parts; so that where sand and smaller kinds of sea-weeds are used, if they are laid on land in proper quantities it will enrich it for six or seven years; but shells, corals, and other hard bodies, will continue many years longer.

In dunging of land, I have frequently observed in several parts of England, but especially in Cambridge-shire, a very wrong custom continued, by carrying and laying the dung on the land about Midsummer, and spread abroad perhaps a month or six weeks before the ground is ploughed; in which time the sun exhales all the goodness of the dung, so that what remains is of little service to the land. Therefore when dung or any other Manure is used, it should not be laid on the ground until the last time of ploughing, when it should be buried as soon as possible, to prevent the evaporation of the salts. Indeed, where shells, corals, or any other hard substances, are used for Manure, if these are spread abroad some months before the ground is ploughed, the sun, rain, or frost will cause them to pulverize much sooner than when they are buried and excluded from the air.

The dressing of Grass ground in summer, soon after the crop of hay is taken off the land, is equally bad; for before Michaelmas the sun will have dried and exhaled most of the goodness, if the dressing is of dung or any other soft Manure, so that the ground will receive small advantage from it; and yet this method is too generally practised.

M A P L E. See ACER.

M A R A C O C K. See PASSIFLORA.

M A R A N T A. Plum. Nov. Gen. 16. tab. 36. Lin. Gen. Plant. 5. Indian Arrow-root.

The CHARACTERS are,

It hath a small three-leaved empalement sitting upon the germen; the flower hath one petal, which is of the grinning kind, having an oblong compressed tube, which is oblique and turned inward; the rim is cut into six small segments, representing a lip flower, the two side segments being the largest. It has one membranaceous stamina, appearing like a segment of the petal, with a linear summit fastened to the border. It hath a roundish germen situated under the flower, supporting a simple style the length of the petal, crowned by a three-cornered stigma.

M A R

The germen afterward turns to a roundish three-cornered capsule with three valves, containing one hard rough seed.

This genus of plants is ranged in the first section of Linnæus's first class, intitled Monandria Monogynia, which includes those plants whose flowers have but one stamina and one style.

The SPECIES are,

1. MARANTA (*Arundinacea*) culmo ramoso. Lin. Sp. 2. *Indian Arrow-root with branching stalks.* Maranta Arundinacea cannaçori folio. Plum. Nov. Gen. 16. *Maranta with a leaf of the Indian flowering Reed.*
2. MARANTA (*Galanga*) culmo simplici. Lin. Sp. 3. *Indian Arrow-root with a simple stalk.* Canna Indica, radice albâ alexipharmica. Sloan. Cat. Jam. 122. *Indian Arrow-root.*

The first sort was discovered by Father Plumier in some of the French settlements in America, who gave it this name, in honour of one Bartholomew Maranta, an ancient botanist. The seeds of this kind were sent to Europe by the late Dr. William Houstoun, who found the plant growing in plenty near La Vera Cruz in New Spain.

This hath a thick, fleshy, creeping root which is very full of knots, from which arise many smooth leaves, which are six or seven inches long, and three broad toward their base, lessening toward each end, terminating in points. They are of the consistence and colour of those of the Reed, and stand upon Reed-like foot-stalks, which arise immediately from the root; between these come out the stalks, which rise near two feet high; these divide upward into two or three smaller, and are garnished at each joint with one leaf of the same shape with the lower, but are smaller. The ends of the stalks are terminated by a loose bunch of small white flowers, standing upon foot-stalks which are near two inches long. The flowers are cut into six narrow segments, which are indented on their edges; these sit upon the embryo, which afterward turns to a roundish three-cornered capsule, inclosing one hard rough seed. It flowers here in June and July.

The other sort was brought from some of the Spanish settlements in America, into the islands of Barbadoes and Jamaica, where it is cultivated in their gardens as a medicinal plant, it being a sovereign remedy to cure the bite of wasps, and to extract the poison of the Manchineel-tree. The Indians apply the root to expel the poison of their arrows, which they use with great success. They take up the roots, and after cleansing them from dirt, they mash them, and apply it as a poultice to the wounded part, which draws out the poison and heals the wound. It will also stop a gangrene, if it is applied before it is gone too far, so that it is a very valuable plant.

This sort is very like the first, but has a single stalk; the flowers are smaller, and the segments of the petals are entire, in which their principal difference consists; it flowers also at the same time.

These plants being natives of a warm country, are very tender, and therefore will not live in this climate, unless they are preserved in stoves. They may be propagated by their creeping roots, which should be parted in the middle of March, just before they begin to push out new leaves. These roots should be planted in pots filled with light rich earth, and plunged into a moderate hot-bed of tanners bark, observing now and then to refresh them with water; but it must not be given to them in large quantities, for too much moisture will soon rot the roots, when they are in an unactive state. When the green leaves appear above ground, the plants will require more frequently to be watered, and they should have free air admitted to them every day, in proportion to the warmth of the season, and the heat of the bed in which they are placed. As the plants advance in strength, they should have a greater share of air, but they must constantly remain in the stove plunged in the tan, otherwise they will not thrive; for when the pots are placed on shelves in the stove, the moisture passes too soon from the fibres, which

M A R

which generally spread on the sides and bottoms of the pots, so that the plants do not receive much nourishment from the water. But where they are constantly kept in the tanners bark, and have proper air and moisture, they will thrive, so as from a small root to fill the pot in which it was planted, in one summer. About Michaelmas the first sort will begin to decay, and in a short time after the leaves will die to the ground, but the pots must be continued all the winter in the bark-bed, otherwise the roots will perish; for although they are in an unactive state, yet they will not keep very long from shrinking, when taken out of the ground; and if the pots are taken out of the tan, and placed in any dry part of the stove, the roots often shrivel and decay; but when they are continued in the tan-bed they should have but little water given to them when their leaves are decayed, lest it rot them. The first sort doth flower constantly in July or August, and will often produce ripe seeds in England; but the second sort doth not flower so constant, nor do the flowers appear so conspicuous, being very small and of a short duration. This sort never hath produced any seeds in England, nor could I ever observe any rudiment of a seed-vessel succeeding the flower. The green leaves abide on this sort most part of the winter, seldom decaying till February; and sometimes will continue green until fresh leaves come up, and thrust the old ones off; in which particular there is a more remarkable difference between the two sorts, than can be observed in the face of plants.

MARJORAM. See **ORIGANUM**.

MARLE is a kind of clay, which is become fatter, and of a more enriching quality, by a better fermentation, and by its having lain so deep in the earth as not to have spent or weakened its fertilizing quality by any product.

Marle is supposed to be much of the nature of chalk, and is believed to be fertile from its salt and oily quality; and that it contracts its salts from the air, and for that reason is the better the longer it is exposed to it.

Marles are of different qualities in different counties of England. There are reckoned to be four sorts of Marles in Sussex, a gray, a blue, a yellow, and a red; of these the blue is accounted the best, the yellow the next, and the gray the next to that; and as for the red, that is the least valuable.

The Marle in Sussex is most like fullers earth, and therefore must certainly be the fattest, whereas that in the north country runs much upon the loam.

In Cheshire they reckon six sorts of Marle:

1. The cowshut Marle, which is of a brownish colour, with blue veins in it, and little lumps of chalk or lime stone; it is commonly found under clay, or low black land, seven or eight feet deep, and is very hard to dig.

2. Stone, slate, or flag Marle, which is a kind of soft stone, or rather slate, of a blue or bluish colour, that will easily dissolve with frost or rain. This is found near rivers and the sides of hills, and is a very lasting sort of Marle.

In Staffordshire they esteem the dice or slate Marle better than the clay Marle, and reckon the blue best for arable land, and the gray for pasture.

3. Peat Marle, or delving Marle, which is close, strong, and very fat, of a brown colour, and is found on the sides of hills, and in wet boggy grounds, which have a light sand in them about two feet or a yard deep. This is accounted the strongest of all Marles, and is very good for sandy land, but the land must have a double quantity laid on.

4. Clay Marle; this resembles clay, and is pretty near akin to it, but is fatter, and sometimes mixed with chalk stones.

5. Steel Marle, which lies commonly in the bottom of pits that are dug, and is of itself apt to break into cubical bits; this is sometimes under sandy land.

6. Paper Marle, which resembles leaves or pieces of brown paper, but something of a lighter colour; this

M A R

lies near coals. This sort is less esteemed, it being hard to be got.

The properties of any sorts of Marles, and by which the goodness of them may be best known, are better judged of by their purity and uncompoundedness, than their colour: as if it will break in pieces like dice, or into thin flakes, or is smooth like lead ore, and is without a mixture of gravel or sand; if it will shake like slate stones, and shatter after wet, or will turn to dust when it has been exposed to the sun: or will not hang and stick together when it is thoroughly dry, like tough clay; but is fat and tender, and will open the land it is laid on, and not bind; it may be taken for granted, that it will be beneficial to it.

Some advise to try the goodness of Marle, by putting some of it in a glass of water; and they account it to be good, if it be so tender, that the lumps break, and dissolve as soon as it comes to the bottom; they also reckon it a good sign, if it sparkle in the water, and feel fat between the fingers; but the surest sign of its goodness is, if it dissolve by wet or frost. The strength of Marle may also be known, by putting a lump of it in a glass of good vinegar, where, if the fermentation is great, it is a sure sign of the goodness of the Marle.

Some approve of marling land shallow, because they say, it is apt to work downwards; others of laying it in deep at first, because the sun wastes the fatness of it.

Some recommend Marles for the improving of sandy loose land, but the surest way to know what lands it will best suit with, is to try with a little of it on lands supposed to be of a contrary nature to it.

Marles do not make so good an improvement of lands the first year as afterwards.

Some advise, first to burn the Marle before it is laid on the lands; which if it be done, one load will go as far as five.

The quantity of Marle ought to be in proportion to the depth of the earth, for over-marling has often proved of worse consequence than under-marling, especially where the land is strong; for by laying it in too great quantities, or often repeating the marling, the land has become so strong, and bound so closely, as to detain the wet like a dish, so that the owners have been obliged to drain the ground at a great expence, and have often been obliged to lower their rents; but in sandy land there can be no danger in laying on a great quantity, or repeating it often, for it is one of the best dressings for such land.

MARRUBIASTRUM, Bastard Horehound. See **SIDERITIS**.

MARRUBIUM. Tourn. Inst. R.H. 192. tab. 91. Lin. Gen. Plant. 640. Pseudodictamnus. Tourn. 188. tab. 89. Lin. Gen. Plant. 640. [Some derive the name of מרר, *Heb.* Marrob, i. e. bitter juice; others from the Latin word Marcidum, because the leaves of this plant are so wrinkled, that they appear to be withering.] Horehound.

The **CHARACTERS** are,

The empalement of the flower is funnel-shaped, of one leaf, and equal at the brim, which spreads open. The flower is of the lip or grinning kind, with a cylindrical tube opening at the brim, where it is divided into two lips, the upper being very narrow and acute, the under broad, reflexed, and cut into three segments, the middle one is broad and indented. It has four stamina, which are under the upper lip, two of which are a little longer than the other, terminated by simple summits. It hath a four-pointed germen, supporting a slender style of the same length, and situated with the stamina, crowned by a bifid stigma. The germen afterward turns to four oblong seeds, sitting in the empalement.

This genus of plants is ranged in the first section of Linnaeus's fourteenth class, intitled *Didynamia Gymnospermia*, which includes those plants whose flowers have two long and two short stamina, which are succeeded by naked seeds sitting in the empalement.

The

M A R

The SPECIES are,

1. MARRUBIUM (*Vulgare*) dentibus calycinis setaceis uncinatis. Hort. Cliff. 312. *Horehound with hooked bristly indentures to the empalement.* Marrubium album vulgare. C. B. P. 230. *Common white Horehound.*
2. MARRUBIUM (*Peregrinum*) foliis ovato-lanceolatis serratis, calycum denticulis setaceis. Hort. Cliff. 311. *Horehound with oval, spear-shaped, sawed leaves, and bristly indentures to the empalement.* Marrubium album latifolium peregrinum. C. B. P. 230. *Broad-leaved, foreign, white Horehound.*
3. MARRUBIUM (*Creticum*) foliis lanceolatis dentatis, verticillis minoribus, dentibus calycinis setaceis, erectis. *Horehound with spear-shaped indented leaves, smaller whorls, and erect bristly indentures to the empalements.* Marrubium album angustifolium peregrinum. C. B. P. 230. *Narrow-leaved, foreign, white Horehound.*
4. MARRUBIUM (*Alysson*) foliis cuneiformibus, quinque verticillis involucri destitutis. Hort. Cliff. 311. *Horehound with wedge-shaped plaited leaves, with five indentures, and the whorls destitute of covers.* Marrubium alysson dictum, foliis profundè incisis. H. L. *Horehound, called Madwort, with leaves which are deeply cut on their sides.*
5. MARRUBIUM (*Supinum*) dentibus calycinis setaceis rectis villosis. Hort. Cliff. 312. *Horehound with hairy, erect, bristly indentures to the empalement.* Marrubium Hispanicum supinum, foliis sericeis argenteis. Tourn. 193. *Low Spanish Horehound with silken silver-coloured leaves.*
6. MARRUBIUM (*Candidissimum*) foliis subovatis lanatis superne emarginato-crenatis, denticulis calycinis subulatis. Hort. Cliff. 312. *Horehound with woolly leaves almost oval, the upper parts of which are indented and crenated, with awl-shaped indentures to the empalements.* Marrubium album candidissimum & villosum. Tourn. Cor. 1. *Whitest and villose Horehound.*
7. MARRUBIUM (*Hispanicum*) calycum limbis patentibus, denticulis acutis. Hort. Cliff. 312. *Horehound with spreading borders to the empalement, and acute indentures.* Marrubium album rotundifolium Hispanicum. Par. Bat. 201. *Round-leaved Spanish Horehound.*
8. MARRUBIUM (*Crispum*) calycum limbis planis villosis, foliis orbiculatis rugosis, caule herbaceo. *Horehound with a plain hairy border to the empalement, round rough leaves, and an herbaceous stalk.* Pseudodictamnus Hispanicus, foliis crispis & rugosis. Tourn. Inst. 188. *Spanish Bastard Dittany, with rough curled leaves.*
9. MARRUBIUM (*Suffruticosum*) calycum limbis planis villosis, foliis cordatis rugosis incanis, caule suffruticoso. *Horehound with the border of the empalement plain and hoary, heart-shaped, rough leaves, and a shrubby stalk.* Pseudodictamnus Hispanicus, amplissimo folio candidante & villoso. Tourn. Inst. R. H. 118. *Spanish Bastard Dittany, with a very large hoary leaf.*
10. MARRUBIUM (*Pseudodictamnus*) calycum limbis planis villosis, foliis cordatis, caule fruticoso. Hort. Cliff. 312. *Horehound with a plain hairy border to the empalement, heart-shaped leaves, and a shrubby stalk.* Pseudodictamnus verticillatus inodorus. C. B. P. 232. *Whorled unsavoury Bastard Dittany.*
11. MARRUBIUM (*Acetabulosum*) calycum limbis tubo longioribus membranaceis, angulis majoribus rotundatis. Lin. Sp. Plant. 584. *Horehound with a membranaceous rim to the empalement longer than the tube, and larger rounder angles.* Pseudodictamnus acetabulis Moluccæ. C. B. P. 222. *Bastard Dittany, with a pan or hollow of Molucca Baum.*

The first sort is the Prasium, or white Horehound of the shops. This grows naturally in most parts of England, so is seldom propagated in gardens. It hath a ligneous fibrous root, from which come out many square stalks a foot or more in length, which branch out upward, and are garnished with hoary roundish leaves, indented on the edges, placed opposite. The flowers grow in very thick whorls round the stalks at each joint; they are small, white, and of the lip kind, standing in stiff hoary empalements, cut into ten parts at the top, which end in stiff bristles; these are succeeded by four oblong black seeds sitting

M A R

in the empalement. It flowers in June, and the seeds ripen in autumn.

The second sort grows naturally in Italy and Sicily; this rises with square stalks near three feet high, which branch much more than the first; the leaves are rounder, whiter, and stand farther asunder; the whorls of flowers are not so large, but the flowers have longer tubes.

The third sort grows naturally in Spain and Portugal; this rises with slender hoary stalks near three feet high; the leaves are very hoary, much longer and narrower than those of the second; the whorls of flowers are smaller, the bristly indentures of the empalement are longer and erect; the whole plant has an agreeable flavour.

The fourth sort grows naturally in Spain and Italy; this is a biennial plant, whose stalks are about the same length as those of the first; the leaves are wedge-shaped, hoary, and obtusely indented; the whorls of flowers are small, and have no covers. The flowers stand looser in the whorls, and the cuts of the empalement end in very stiff prickles, which spread open; the flowers are purple, and larger than those of the first sort.

The fifth sort grows naturally in the islands of the Archipelago; the stalks of this are seldom above eight or nine inches long, covered with a soft hoary down; the leaves are small, roundish, and very soft to the touch; they are hoary, and indented on the edges. The whorls of flowers are small, very downy, and white; the flowers are small and white.

The sixth sort grows naturally in Spain; this hath stalks about the same length as the first; the leaves are nearly oval, woolly, and crenated toward the top, and the empalement of the flowers are awl-shaped.

The seventh sort grows naturally in Istria, from whence I received the seeds. The stalks of this grow more erect than those of the common sort: the leaves are rounder and more sawed on the edges; the empalement of the flowers spread open, ending in acute segments. The flowers are like those of the common sort; the whole plant is very hoary.

The eighth sort grows naturally in Spain and Sicily; this sends out many stiff roundish stalks, which rise more than two feet high, covered with a white cottony down; the leaves are almost round, rough on their upper side, and woolly on their under; the whorls of flowers are large, the borders of the empalement are flat and hairy; the tube of the flower is scarce so long as the empalement, so the two lips are but just visible.

The ninth sort grows naturally in Spain; the stalks of this are shrubby, and rise near three feet high, dividing into small branches; the leaves are heart-shaped and rough on their upper side, but hoary on their under; the whorls of flowers are large, the borders of the empalements flat and hairy; the tube of the flower is longer, and the flowers are larger than those of the former sort; they are of a pale purple colour, and their upper lips are erect.

The tenth sort grows naturally in Sicily, and the Islands of the Archipelago. This rises with a shrubby stalk two feet high, which divides into many branches, garnished with small heart-shaped leaves, fitting pretty close to the stalks: the whorls of flowers are not so large as those of the two former sorts. The rim of the empalements are flat. The flowers are white, and the whole plant is very hoary.

The eleventh sort grows naturally in Crete; this hath very hairy stalks which rise about two feet high, garnished with heart-shaped leaves, which are rough on their upper side, but hoary on their under. The whorls of flowers are large, the border of the empalements flat, and cut into many segments, which are membranaceous, angular, and rounded at the top. The flowers are small, of a pale purple colour, but scarce appear out of their empalements, and their upper lips are erect.

The

The first sort is what the College of Physicians has directed to be used in medicine. The leaves and tops of the plants are esteemed hot and dry, pectoral, and good to free the lungs from thick viscid phlegm, and thereby to help old coughs, especially in cold moist constitutions, the juice being made into a syrup with sugar or honey; they open obstructions of the liver and spleen, and are very serviceable against the dropsy, jaundice, green sickness, and obstructions of the catamenia, and suppression of the lochia, and other distempers of the female sex, for which few herbs go beyond this. The officinal preparation is the syrupus de Prassio.

The fourth sort is supposed to be Galen's Madwort; this was by the antients greatly recommended for its efficacy in curing of madness, and some few of the moderns have prescribed it in the same disorder, but at present it is seldom used; it is a biennial plant, which generally perishes after it hath perfected seeds. All these plants are preserved in botanic gardens for the sake of variety, but there are not above two of the sorts which are cultivated in other gardens; these are the tenth and eleventh sorts, whose stalks are shrubby; the plants are very hoary, so make a variety when intermixed with other plants; these very rarely produce seeds in England, so are propagated by cuttings, which, if planted in a shady border the middle of April, will take root pretty freely.

They are somewhat tender, so in very severe winters are killed, unless they are screened from the hard frosts, especially those plants which grow in good ground, where they grow luxuriant in summer, so their branches are more replete with juice, and very liable to suffer by cold; but when they are in a poor dry rubbish, the roots will be short, firm, and dry, so are seldom injured by cold, and will continue much longer than those in better ground.

The other sorts are easily propagated by seeds, which should be sown on a bed of poor earth in the spring, and when the plants come up they must be kept clean from weeds; and where they are too close they should be thinned, leaving them a foot and a half asunder, that their branches may have room to spread; after this they require no other culture; they may also be propagated by cuttings, in the same manner as the other two sorts. If these plants are upon a dry poor soil, they will live several years, but in rich land they seldom last above three or four.

MARRUBIUM NIGRUM. See BALLOTE.

MARTAGON. See LILIUM.

MARTYNIA. Houst. Gen. Nov. Martyn. Dec. 1.

42. [This name was given by the late Dr. William Houstoun to this genus of plants, which he discovered in America, in honour of his friend Mr. John Martyn, who was Professor of Botany at Cambridge.]

The CHARACTERS are,

The empalement of the flower is cut into five parts, three of them are erect, and two reflexed. The flower hath one petal, which is bell-shaped, with a large swelling tube, at the base of which is situated a gibbous nectarium. The rim of the petal is cut slightly into five obtuse segments, two of which are turned upward, the other three downward, representing a lip flower. It hath four slender incurved stamina, which are inflexed into each other, terminated by summits, which are connected together. It hath an oblong germen situated under the flower, supporting a short style, crowned by a plain stigma. The empalement afterward turns to an oblong gibbous capsule, which divides into two parts, including a hard nut, shaped like the body of a stag beetle, with two incurved strong horns at the end, having four cells, two of which are generally barren, the other two have one oblong seed in each.

This genus of plants is ranged in the second section of Linnæus's fourteenth class, which includes the plants whose flowers have two long and two short stamina, and the seeds are included in a capsule.

The SPECIES are,

1. MARTYNIA (*Annua*) caule ramoso, foliis angulatis. Lin. Sp. Plant. 618. *Martynia with a branching stalk and angular leaves.* *Martynia annua villosa* & vis-

cosa, folio subrotundo, flore magno rubro. Houst. *Annual, hairy, viscous Martynia, with a roundish leaf, and a large red flower.*

2. MARTYNIA (*Perennis*) caule simplici, foliis ferratis. Lin. Sp. Plant. 618. *Martynia with a single stalk and sawed leaves.* *Martynia foliis ferratis.* Lin. Hort. Cliff. *Martynia with sawed leaves.*

3. MARTYNIA (*Louisiana*) caule decumbente ramosa, foliis integris fructibus longissimis. *Martynia with a decumbent branching stalk, entire leaves, and very long fruit.* The first of these plants was discovered by the late Dr. William Houstoun, near La Vera Cruz, in New Spain, from whence he sent the seeds into England, which succeeded very well in the Physic Garden at Chelsea; and in the year 1731, several of these plants were raised, which produced their beautiful flowers, and perfected their seed, from whence several plants were raised the succeeding year.

This rises with a strong, herbaceous, hairy stalk near three feet high, which divides upward into three or four large branches, garnished with oblong oval leaves, cut into angles on their sides; they are five inches long, and three inches and a half broad at their base, where they are broadest, ending in obtuse points; they are hairy, and very viscous, sticking to the fingers if handled. The flowers are produced in short spikes from the forks of the branches, and also at their tops; they are shaped like those of the Foxglove, but are of a paler purple colour; these are succeeded by oblong oval capsules, which are thick, tough, and clammy; these, when ripe, divide into two parts, leaving a large hard nut hanging on the plant, about the size, and much of the same form; as the stag beetle, with two strong crooked horns at the end. The nut has two deep longitudinal furrows on the sides, and several smaller crossing each other in the middle. It is so hard, that it is with difficulty cut open without injuring of the seeds: within are four oblong cells, two of which have generally a single oblong seed in each, but the other two are abortive. If the plants are brought forward in the spring, they will begin to shew their flowers in July, which are first produced at the division of the branches, and afterward at the extremity of each branch, so there will be a succession of flowers on the same plant till the end of October, when the plants decay.

The second sort was discovered by Mr. Robert Millar, growing naturally about Carthage in New Spain, from whence he sent the seeds to Europe; this hath a perennial root and an annual stalk, which decays every autumn, and new ones arise in the spring. The roots of this plant are thick, fleshy, and divided into knots, which are scaly, somewhat like those of Toothwort; these send up several stalks, which grow about a foot high; they are thick, succulent, and of a purplish colour, garnished with oblong thick leaves, whose base sits close to the stalk; they are sawed on their edges, rough on their upper side, where they are of a dark green, but their under side is purplish. The stalk is terminated by a short spike of blue flowers, which are bell-shaped, and do not spread open at the rim so much as the former sort; these usually appear in July or August, but are not succeeded by seeds in England.

The first sort, being an annual plant, is only propagated by seed, which should be sown in pots filled with light rich earth, and plunged into a hot-bed of tanners bark, where (if the earth is duly watered to promote the vegetation of the seed) the plants will appear in about three weeks or a month, and will grow pretty fast if the bed is warm; they should therefore be transplanted in a little time after they come up, each into a separate pot filled with light rich earth, and then plunged into the hot-bed again, observing to water them well, as also to shade them from the sun until they have taken new root; after which time they should have a large share of fresh air admitted to them in warm weather, by raising the glasses of the hot-bed every day: with this management the plants will make great progress, so as to

M A R

fill the pots with their roots in about a month or six weeks time, when they should be shifted into pots about a foot diameter at the top, which should be filled with light rich earth, and then plunged into the hot-bed in the bark-stove, where they should be allowed room, because they put out many side branches, and will grow three feet high or more, according to the warmth of the bed, and the care which is taken to supply them constantly with water; and should be constantly kept in the tan-bed, giving them plenty of free air at all times when the weather is warm, but they will not bear to be exposed abroad in this country; when these plants thrive well they will send out many side branches, which will all of them produce small spikes of flowers; but it is only from the first spike of flowers that good seeds can be expected in this country, so that particular care should be taken, that none of these are pulled off or destroyed, because it is very difficult to obtain good seeds here; and I believe few of those that are produced on the side branches in the natural country of their growth, are duly ripened; for, I have received a great quantity of these seeds from abroad, which have appeared to be very good, and yet few of them have grown.

The seeds of these plants have a strong green covering on them, as thick as the outer covering of an Almond, and when the seeds are ripe, the covering opens, and lets the seeds fall, in the same manner as the covering of Almonds, Walnuts, &c. In each covering there is one hard nut, in shape somewhat like a beetle, having two sharp crooked horns at one end. This nut contains four embryos, but there are seldom more than two seeds which are perfect in any of them. However, when they are sown, the whole nut must be planted, for it is so hard, that it is almost impossible to take out the seeds without spoiling them; so where there are two plants produced from the same nut, they are easily separated, especially if they are transplanted while young. These seeds will continue good for some years, for I sowed a pretty large quantity of them in the year 1734, part of which I sowed the following year, but had not one plant produced from them; the remainder of the seeds I divided, and sowed some of them every succeeding year, without any success, until the year 1738, when I sowed all the seeds I had left, from which I had one plant produced; so that if the seeds are good, it is evident they will grow when they are four years old; therefore, whenever we receive good seeds from abroad, or save any in this country which are perfectly ripened, it will be proper to preserve some of them for a year or two, lest a bad season should happen, when the plants may not perfect their seeds; so that if this precaution be not taken, the species may be lost in Europe.

The second sort dies to the root every winter, and rises again the succeeding spring; this must be constantly preserved in the stove, and plunged into the bark-bed, otherwise it will not thrive in this country. During the winter season, when the plants are decayed, they should have but little water given to them, for at that time it will rot the roots. In the middle of March, just before the plants begin to shoot, is the proper season to transplant and part the roots, when they should be planted into pots of a middle size, filled with light rich earth, and then plunged into the bark-bed, which should at this time be renewed with some fresh tan. When the plants come up, they must be frequently refreshed with water, but it must not be given to them in large quantities, lest it rot their tender roots; and as the warmth of the season increases, it will be proper to admit a large share of fresh air, which will greatly strengthen the plants; they must also be placed in the tan-bed, where they are not over-hung, or shaded by other plants; nor should they be shifted or transplanted when they are in leaf, for that will prevent their flowering. As the roots of this plant increase very fast, there is no necessity for using other methods to propagate it; otherwise

M A T

the shoots of the young stalks will take root, if they are planted in pots filled with light earth, and plunged into a hot-bed during any of the summer months.

The third sort grows naturally in Louisiana, from whence the seeds were brought to France. This is an annual plant, having a succulent viscous stalk, which divides into many branches; these thick succulent stalks become too weighty for the stalk to support them, whereby the stalk generally is brought to the ground, unless it is well supported: the leaves are large, viscous, and hairy; some of them are cut into angles, but for the most part they are entire, five or six inches long, and four broad in the middle. The flowers are produced from the forks of the stalk in short spikes; they are of a pale red colour, and in shape and size like those of the first sort; they are succeeded by fruit four or five inches long, having a thick green cover, which parts and falls off when ripe, leaving a rough beetle-shaped vessel, having two very long horns at the end, opening in two parts, containing several oval seeds, covered with a black skin, which must be taken off before the seeds are sown.

This being an annual plant, should be brought forward in the spring, by sowing the seeds on a hot-bed the latter end of March; and when the plants come up, they should be treated almost in the same manner as the first, with this difference only, that being more hardy than the first, the plants should have more air admitted to them, to prevent their drawing up weak; nor should they have too much water in summer, which is apt to rot their succulent stems before the seeds are perfected.

MATRICARIA. Tourn. Inst. R. H. 493. tab. 281. Lin. Gen. Plant. 867. [so called from the matrix, because this plant is very good against diseases of the womb; and for the same reason it is called Parthenium, of Παρθένος, a virgin.] Feverfew; in French, *Matricaire*.

The CHARACTERS are,

It hath a compound flower. The ray, or border, is composed of many female half florets, and the disk, which is hemispherical, of hermaphrodite florets; these are included in one common hemispherical empalement, composed of linear scales, nearly equal. The female half florets are tongue-shaped, and indented in three parts at the end; these have a naked germen, supporting a slender style, terminated by two twisted stigmas. The hermaphrodite florets are tubulous, funnel-shaped, and cut into five parts at the brim, which spread open; they have each five hairy short stamina, terminated by cylindrical summits, and an oblong naked germen, with a slender style, crowned by a bifid spreading stigma. The germen of both turn to single, oblong, naked seeds.

This genus of plants is ranged in the second section of Linnæus's nineteenth class, which includes the plants with compound flowers, whose stamina and styles are connected, and the florets are all fruitful.

The SPECIES are,

1. MATRICARIA (*Parthenium*) foliis compositis planis, foliolis ovatis incis, pedunculis ramosis. Hort. Cliff. 416. *Feverfew with plain compounded leaves, whose lobes are oval and cut, having branching foot-stalks.* Matricaria vulgaris, seu fativa. C. B. P. 133. *Common, or Garden Feverfew.*
2. MATRICARIA (*Maritima*) receptaculis hemisphæricis, foliis bipinnatis subcarnosis, supra convexis, subtus carinatis. Lin. Sp. Plant. 891. *Feverfew with hemispherical receptacles, doubly winged leaves, which are fleshy, and convex on their upper side, but keel-shaped below.* Chamæmelum maritimum perenne humiliss, foliis brevioribus

brevioribus crassis obscure virentibus. Raii Syn. Ed. 3. p. 186. Dwarf, perennial, maritime Chamomile, with short, thick, dark green leaves.

3. MATRICARIA (*Indica*) foliis ovatis sinuatis angulis ferratis acutis. *Feverfew with oval, sinuated, angular, acutely-sawed leaves.* Matricaria latiore folio, flore pleno. Mor. Hist. 3. p. 33.

4. MATRICARIA (*Argentea*) foliis bipinnatis, pedunculis solitariis, Hort. Cliff. 415. *Feverfew with winged leaves, and single foot-stalks to the flowers.* Chamæmelum Orientale incanum, Millefolium folio. Tourn. Cor. 37.

5. MATRICARIA (*Americana*) foliis lineari-lanceolatis integerrimis, pedunculis unifloris. *Feverfew with entire spear-shaped leaves, and foot-stalks with one flower.*

The first sort is the common Feverfew, which is directed to be used in medicine. It grows naturally in lanes, and upon the side of banks in many parts of England, but is frequently cultivated in the physic-gardens to supply the markets; this is commonly a biennial plant, which decays soon after it has perfected seeds. The root of this plant is composed of a great number of fibres, which spread wide on every side. The stalks rise upward of two feet high; they are round, stiff, and striated, branching out on every side. The leaves are composed of seven lobes, which are cut into many obtuse segments; they are of a yellowish green colour. The stalks and branches are terminated by the flowers, which are disposed almost in the form of loose umbels, each flower standing upon a separate foot-stalk, about two inches long. The flowers are composed of several short rays, which are white, like those of the Chamomile, surrounding a yellow disk, composed of hermaphrodite florets, which form a hemisphere; these are inclosed in one common scaly empalement, and are succeeded by oblong, angular, naked seeds. It flowers in June, and the seeds ripen in autumn. The whole plant has a strong unpleasant odour. The leaves and flowers of this are used in medicine, and are particularly appropriated to the female sex, being of great service in all cold flatulent disorders of the womb, and hysteric affections, procuring the catamenia, and expelling the birth and secundines.

The following varieties of this plant are preserved in botanic gardens, many of which are pretty constant, if care is taken in saving the seeds; but where the seeds of these plants has been suffered to scatter, it will be almost impossible to preserve the varieties without mixture; but if the seeds are sown upon a fresh spot of ground, where there has not grown any of the plants before, I am inclinable to believe the seeds will produce the same plants as those they were taken from; however, as they are supposed to be only varieties, so I shall only just insert them here, for the use of those who are curious in collecting the varieties.

1. Feverfew with very double flowers.
2. Feverfew with double flowers, whose borders, or rays are plain, and the disk fistular.
3. Feverfew with very small rays.
4. Feverfew with very short fistular florets.
5. Feverfew with naked heads, having no rays or border.
6. Feverfew with naked sulphur-coloured heads.
7. Feverfew with elegant curled leaves.

These plants are all propagated by their seeds, which should be sown in March upon a bed of light earth, and, when they are come up, they should be transplanted out into nursery-beds, at about eight inches asunder, where they may remain till the middle of May, when they may be taken up, with a ball of earth to their roots, and planted in the middle of large borders, where they will flower in July and August; and, if the autumn be favourable, will produce ripe seeds the same year. But it is not advisable to permit them to seed, which often weakens and decays the roots; therefore, when their flowers are past, you should cut down their stems, which will cause them to push out fresh heads, whereby the roots may be maintained.

When the different varieties of these plants are inter-

mixed with other plants of the same growth, they make a handsome appearance during the season of flowering, which commonly continues a full month, or more, which renders them more valuable. But as their roots seldom abide more than two, or at most three years, fresh plants would be raised from seeds to supply their places; for although they may be propagated by parting their roots either in spring or autumn, yet these seldom make so good plants as those obtained from seeds; but the second variety seldom produces any good seeds, therefore that must be propagated in this manner, or by planting cuttings in the spring or summer months, which will take root, and make good plants.

The second sort grows naturally near the sea, in several parts of England. I have observed it upon the Sussex coast in great plenty, from whence I brought the plants, which were of no longer duration in the garden than two years, though in their native soil they may continue longer. The stalks of this plant branch out pretty much, and spread near the ground; they are garnished with dark green leaves, which are composed of many double-wings, or pinnæ, like those of the common Chamomile, but are much thicker in substance; they have their edges turned backward, so are convex on their upper surface, and concave on their under. The flowers are white, like those of the common Chamomile, and are disposed almost in the form of an umbel; they appear in July, and the seeds ripen in autumn.

This plant is seldom cultivated but in botanic gardens for variety. It may be propagated by seeds, which may be sown either in autumn, soon after they are ripe, or in the spring, upon a bed of common earth, in almost any situation; and when the plants come up, they will require no other care but to thin them where they are too close, and keep them clean from weeds.

The third sort grows naturally in many parts of India, I received it from Nimpu, where it grows plentifully; this plant rises a foot and a half high, dividing into many branches, garnished with angular oval leaves, which are acutely sawed on their edges, and are of a pale colour; the flowers are produced on foot-stalks which arise from the wings of the leaves, and also terminate the branches; these are, in all I have yet seen, very double, and full as large as those of the double sort before-mentioned; these appear in July, and in favourable seasons are succeeded by seeds which ripen late in the autumn.

This sort is propagated by seeds, which should be sown in the spring upon a moderate hot-bed, and when the plants come up, they must be treated in the manner already directed for the Chrysanthemum Coronarium, with which culture they will thrive and flower very well.

The fourth sort grows naturally in the east; this sort rises a foot high, having winged leaves of a silver colour, which are for the most part placed opposite; the foot-stalks of the flowers arise single from the side of the branches, each supporting one white flower. This flowers in July, and in warm seasons will sometimes perfect seeds in autumn.

The seeds of this sort should be sown in April, on a bed of light earth, in a good exposure; and when the plants are grown of a proper size to remove, they should be planted in the borders of the flower-garden; where, if they are kept clean from weeds, they will flower and perfect their seeds.

The fifth sort grows naturally in North America; this is a perennial plant, whose stalks and leaves decay in the autumn, and new ones come out again in the spring; the stalks rise a foot and a half high, and divide upward into several forked branches; at each of these divisions is placed one linear spear-shaped leaf about two inches long, and a quarter of an inch broad, entire on the edges, and of a deep green. The branches are terminated by single foot-stalks, each supporting one blue flower, very like those of some kind of Starwort; but the empalement being scaly,

scaly, and the seeds having no down, occasions its being here placed. The flowers appear in July and August, and the seeds ripen in the autumn.

This is propagated by seeds, which, if sown in the autumn, soon after they are ripe, will more certainly succeed than when sown in the spring; they should be sown in the full ground, and when the plants are fit to remove, if they are planted in the borders of the flower-garden, they will continue some years without protection, and annually produce flowers and seeds.

MATTED ROOTS are such as are entangled or plaited together.

MAUROCENIA. Lin. Gen. Plant. Edit. 2. 289. *Frangula*. Hort. Elth. 121. The Hottentot Cherry, vulgo.

The CHARACTERS are,

The empalement of the flower is of one leaf, cut into five segments, and is permanent. The flower hath five oval petals, which spread open. It hath five stamina, which are situated between the petals, crowned by obtuse summits. In the center is situated a roundish germen, having no style, crowned by a trifid stigma. The germen afterward turns to an oval berry with one or two cells, each containing a single oval seed.

This genus of plants is ranged in the third section of Linnæus's fifth class, which includes the plants whose flowers have five stamina and three styles or stigmas; and in the last edition of his Genera, he has joined it to the *Cassine*, making them the same; but as the flower of *Cassine* has but one petal, and the flower of these have five; and the berries of the former three cells, and those of this but one or two, therefore I have separated them.

The SPECIES are,

1. MAUROCENIA (*Frangula*) foliis subovatis integerrimis, floribus confertis lateralibus. *Maurocenia* with entire leaves which are almost oval, and flowers growing in clusters on the sides of the branches. *Frangula sempervirens*, folio rigido subrotundo. Hort. Elth. 146. tab. 121. Evergreen berry-bearing Alder with a roundish stiff leaf, commonly called Hottentot Cherry.
2. MAUROCENIA (*Phillyrea*) foliis obversè ovatis serratis, floribus corymbosis alaribus & terminalibus. *Maurocenia* with obverse, oval, sawed leaves, and flowers growing in a corymbus at the sides and ends of the branches. *Phillyrea capensis*, folio celastri. Hort. Elth. 315. tab. 236. *Phillyrea* of the Cape with a Staff-tree leaf, by the Dutch called Leplehout.
3. MAUROCENIA (*Cerasus*) foliis ovatis nervosis integerrimis. *Maurocenia* with oval veined leaves, which are entire. *Cerasus Hottentotorum*. Pluk. Almag. 94. The smaller Hottentot Cherry.
4. MAUROCENIA (*Americana*) foliis obversè ovatis emarginatis, floribus solitariis alaribus. *Maurocenia* with obverse oval leaves which are indented at the edges, and flowers growing singly from the sides of the branches. *Frangula* folio subrotundo, rigido subius ferrugineo. Houtt. MSS. Berry-bearing Alder with a roundish stiff leaf, which is of an iron colour on the under side.

The first sort grows naturally at the Cape of Good Hope, where it rises to a considerable height, but here they are rarely more than five or six feet high. The stalk is strong, woody, and covered with a purplish bark, sending out many stiff branches, garnished with very thick leaves, almost oval, standing for the most part opposite; they are about two inches long, and almost as much in breadth, of a dark green colour, and entire. The flowers come out from the side of the old branches, in clusters, three, four, or five, standing upon one common foot-stalk, which is slender, composed of five plain equal petals, ending in acute points; they are first of a greenish yellow colour, but afterward change to white, spreading wide open. In the center is situated the oval germen, crowned by the trifid stigma, and between each petal is situated a stamina; these spread out in the same manner as the petals, and are terminated by obtuse summits. The germen afterward

turns to an oval pulpy berry, some having but one, and others two cells; in each of these is lodged one oval seed. The berries change to a dark purple when they are ripe. This plant flowers in July and August, and the berries ripen in winter.

The second sort is a native of the Cape of Good Hope; this hath a woody stalk, which in this country seldom rises more than five or six feet high, sending out many branches, covered with a dark purplish bark, and garnished with pretty stiff leaves, which are obversely oval, and sawed on their edges, standing opposite; they are about an inch and a half long, and a little more in breadth, of a light green, having short foot-stalks. The flowers are produced in roundish bunches from the side, and at the end of the branches; they are white, and have five small petals which spread open; between these are situated the stamina, which spread in the same manner; these are terminated by obtuse summits. In the center is situated the roundish germen, which is crowned sometimes by a bifid, and at others by a trifid stigma. The flowers appear in July and August, but are not succeeded by berries in England.

The third sort grows naturally at the Cape of Good Hope; this rises with a woody stalk about the same height as the former, dividing into many branches, which are garnished with stiff oval leaves about two inches long, and nearly as much in breadth, of a lucid green colour, and entire, having three longitudinal veins; these are sometimes placed opposite, and at others they are alternate, having a strong margin, or border, surrounding them. This sort hath produced its flowers in England, and I am fully convinced that the characters of the flowers are the same with the others.

The fourth sort was discovered by the late Dr. Houttoun, growing naturally at the Palisadoes in Jamaica, from whence he sent the seeds to Europe; this rises with a woody stalk from fifteen to twenty feet high, covered with a rough brown bark, and divides into many branches, which are garnished with stiff leaves, placed alternately; they are about an inch and a half long, and a little more in breadth, indented at the top, with a stiff reflexed border, of a gray colour on their upper side, but of a rusty iron colour on their under, standing upon short foot-stalks. The flowers come out singly along the side of the branches; they have five small white petals, which end in acute points, and five slender stamina, which spread open, and are terminated by obtuse summits. In the center is situated a roundish germen, supporting a long bifid stigma, which is permanent. The germen afterward turns to a round berry, with one or two cells, each having one oblong seed.

The first sort is too tender to live abroad in England, but as it requires no artificial heat, so may be preserved through the winter in a good green-house, where it deserves a place for the beauty of its leaves, which are very thick, of a deep green, and differing in appearance from every other plant; this may be propagated by laying down those shoots which are produced near the root, but they are long in putting out roots. The shoots should be twisted in the part which is laid, to facilitate their putting out roots; if these are laid down in the autumn, they will put out roots sufficient to remove by the following autumn; it may also be propagated by cuttings, but this is a tedious method, as they are seldom rooted enough to transplant in less than two years. When this is practised, the young shoots of the former year should be cut off, with a small piece of the old wood at the bottom, in the spring, and planted in pots filled with loamy earth, and plunged into a moderate hot-bed, covering the pots with glasses, which should be close stopped down to exclude the external air; they should be pretty well watered at the time they are planted, but afterward they will require but little wet; the glasses over them should be covered every day with mats, to screen the cuttings from the sun during the heat of the

M A R

the day, but in the morning before the sun is too warm, and in the afternoon, when the sun is low, they should be uncovered, that the oblique rays of the sun may raise a gentle warmth under the glasses. With this care the cuttings will take root, but where it is wanting, they seldom succeed. When the cuttings or layers are rooted, they should be each planted in a separate small pot, filled with soft loamy soil, and placed in the shade till they have taken new root; then they may be removed to a sheltered situation, where they may remain during the summer season; and, before the frosts of the autumn come on, they must be removed into the green-house, and treated in the same way as the other plants of that country, giving them but little water in cold weather, and in mild weather admitting the free air. In summer they must be removed into the open air, and placed in a sheltered situation with other exotic plants, and in very warm weather they must be watered three times a week, but it must not be given them too freely at any time. When the plants have obtained strength, they will produce flowers and fruit, which, in warm seasons, will ripen perfectly; and if the seeds are sown soon after they are ripe, in pots, and plunged into the tan-bed in the stove, the plants will come up the spring following, and may then be treated in the same manner as those which are propagated by cuttings and layers.

The second sort is not altogether so hardy as the first, so must have a warmer place in the green-house in winter, and should not be placed abroad quite so early in the spring, nor suffered to remain abroad so late in the autumn, but if the green-house is warm, the plants will require no additional heat. This may be propagated by layers and cuttings, in the same manner as the first, and requires the same care, for the cuttings are with difficulty made to root; nor will the branches which are laid, put out roots in less than a year, and if these are not young shoots, they will not take root.

As this sort does not produce seeds in England, it can be only propagated by layers and cuttings, which being difficult to root, occasions its being scarce at present in Europe.

The third sort is yet more rare than either of the former, and is with greater difficulty propagated, for the layers and cuttings are commonly two years before they get roots sufficient to remove, and as it never produces seeds here, it can be no other way propagated; this is also tenderer than either of the other sorts, so requires a moderate degree of heat in winter, for without some artificial warmth, it will seldom live through the winters in England. In the middle of summer the plants may be placed abroad in a warm situation, but they must be removed into shelter early in the autumn, before the cold nights come on, otherwise they will receive a check, which they will not recover in winter; during the summer season they should be gently watered three times a week in dry weather, but in winter they will require to be seldom watered.

The fourth sort is much more impatient of cold than either of the other, being a native of a warmer country. This is propagated by seeds, which must be procured from the country where it grows naturally, for it does not produce any here. These do not grow the first year, so the seeds should be sown in pots filled with light earth, and plunged into a moderate hot-bed of tanners bark, where they may remain all the summer; and in the autumn they should be removed into the bark-stove, and plunged into the tan-bed between the other pots of plants, in any vacant spaces; there they may remain till spring, when they should be taken out of the stove, and plunged into a fresh hot bed, which will bring up the plants. When these are fit to remove, they should be each transplanted into a separate small pot, filled with a soft loamy earth, and plunged into a hot-bed again, being careful to shade them from the sun till they have taken new root, after which they must be treated in the

M E D

same manner as other tender plants from the same country, always keeping them in the tan-bed; and in winter they must have a temperate warmth, otherwise they will not live here.

All the sorts delight in a soft, gentle, loamy soil, not over stiff, so as to detain the wet; nor should the soil be too light, for in such they seldom thrive. They retain their leaves all the year, so make a good appearance in the winter season, their leaves being remarkably stiff and of a fine green, especially the first sort, whose fruit ripens in winter, which when it is in plenty on the plants, affords an agreeable variety.

MAYS. See ZEA.

MEADIA. Cateb. Carol. 3. p. 1. Dodecatheon. Lin. Gen. Plant. 183.

The CHARACTERS are,

It hath a small involucre of many leaves, in which are many flowers. The flower hath a permanent empalement of one leaf, cut into five long segments which are reflexed. The flower hath one petal, cut into five parts, whose tube is shorter than the empalement, and the limb is reflexed backward. It hath five short obtuse stamina fitting in the tube, terminated by arrow-pointed stigmas, which are connected into a beak, with a conical germen, supporting a slender style longer than the stamina, crowned by an obtuse stigma. The empalement afterward becomes an oblong oval capsule with one cell, opening at the top, and filled with small seeds.

This genus of plants is ranged in the first section of Linnæus's fifth class, which includes those plants whose flowers have five stamina and one style. The title of this genus was given to it by Mr. Mark Cateby, F. R. S. in honour of the late Dr. Mead, who was a generous encourager of every useful branch of science; but being himself no great botanist, Dr. Linnæus was unwilling any plant should bear his name, so he has altered it to that of Dodecatheon, which was a title applied by Pliny to a species of Primrose with a yellow root, and leaves like the Garden Lettuce.

We have but one SPECIES of this genus, viz.

MEADIA (Dodecatheon.) Cateb. Hist. Carol. App. 1. tabi

1. *Meadia. Auricula urfi Virginiana, floribus boraginis, instar rostratis, cyclaminum more reflexis. Pluk. Alm. 62. tab. 79. fol. 6. Bear's-ear of Virginia, whose flower has a beak like that of Borage, and reflexed petals like those of Sowbread.*

This plant grows naturally in Virginia, and other parts of North America, from whence it was sent by Mr. Banister, many years since, to Dr. Compton, Lord Bishop of London, in whose curious garden I first saw this plant growing in the year 1709; after which the plant was for several years lost in England, till within a few years past, when it was again obtained from America, and has been propagated in pretty great plenty. It hath a yellow perennial root, from which comes out several long smooth leaves in the spring, which are near six inches long, and two and a half broad; at first standing erect, but afterward they spread on the ground, especially if the plants are much exposed to the sun; from between these leaves arise two, three, or four flower-stalks, in proportion to the strength of the roots, which rise eight or nine inches high, they are smooth, naked, and are terminated by an umbel of flowers, under which is situated the many-leaved involucre. Each flower is sustained by a pretty long slender foot-stalk which is recurved, so that the flower hangs downward. The flower has but one petal, which is deeply cut into five spear-shaped segments, which are reflexed upward like the flowers of Cyclamen or Sowbread; the stamina, which are five in number, are short, and sit in the tube of the flower, having five arrow-pointed summits, which are connected together round the style, forming a sort of beak. The flowers are purple, inclining to a Peach blossom colour, and have an oblong germen situated in the bottom of the tube, which afterward becomes an oval capsule inclosed by the empalement, with the permanent style on its apex, which, when ripe, opens at the top to let out the

the seeds, which are fastened round the style. This plant flowers the beginning of May, and the seeds ripen in July, soon after which the stalks and leaves decay, so that the roots remain inactive till the following spring.

This plant is propagated by offsets, which the roots put out pretty freely when they are in a loose moist soil and a shady situation; the best time to remove the roots, and take away the offsets, is in August, after the leaves and stalks are decayed, that they may be fixed well in their new situation before the frost comes on. It may also be propagated by seeds, which the plants generally produce in plenty; these should be sown in the autumn soon after they are ripe, either in a shady moist border, or in pots, which should be placed in the shade; in the spring the plants will come up, and must then be kept clean from weeds, and if the season proves dry, they must be frequently refreshed with water; nor should they be exposed to the sun, for while the plants are young, they are very impatient of heat, so that I have known great numbers of them destroyed in two or three days, which were growing to the full sun. These young plants should not be transplanted till their leaves are decayed, then they may be carefully taken up and planted in a shady border, where the soil is loose and moist, at about eight inches distance from each other, which will be room enough for them to grow one year, by which time they will be strong enough to produce flowers, so may then be transplanted into some shady borders in the flower-garden, where they will appear very ornamental during the continuance of their flowers.

At the first many supposed this plant to be tender, so planted it in warm situations and nursed it too much, whereby the plants were often killed; but by experience it is found to be so hardy, as not to be hurt by the severest cold of this country; but it will not thrive in a very dry soil, or where it is greatly exposed to the sun.

MEADOW.

Under the general title of Meadow, is commonly comprehended all pasture land, or at least all Grass land, which is mown for hay; but I chuse rather to distinguish such land only by this appellation, which is so low, as to be too moist for cattle to graze upon them in winter, being generally too wet to admit heavy cattle, without poaching and spoiling the sward; and those Grass lands which are drier, I shall distinguish by the title of pasture.

There are two sorts of Meadows in England, one of which is stiled Water Meadows, and the other are simply called Meadows.

Water Meadows are those which lie contiguous to rivers or brooks, from whence the water can be carried to overflow the Grass at pleasure. Of these there are large tracts in several parts of England, which, if skilfully managed, would become much more profitable to their owners than they are at present, as hath been already mentioned in another place; for nothing can be more absurd than the common practice of flowing these low grounds all the winter, whereby the roots of all the sweetest kinds of Grass are destroyed, and only such Grasses left as are natives of marshes, which are coarse and sour: and if people were curious to examine the herbage of these Water Meadows, they would find the bulk of them composed of bad weeds, such as grow by the sides of rivers, brooks, and ditches, of which the several sorts of Docks make no small share; and although many of these Meadows produce a great burden of what the country people call hay, yet this is only fit for cows, cart-horses, and other animals, which by hard labour and hunger, are driven to eat it; for horses which have been accustomed to feed on good hay, will starve before they will touch it: and after the Grass is mown off these Meadows, and cattle turned in to graze upon them, how common is it to see the land almost covered with these rank weeds, which the cattle never will eat! Which must always be the condition of such Meadows,

where the water is let over them in autumn and winter; for, as the sides of rivers and brooks do every where abound with these rank weeds, whose seeds ripen in autumn, and falling into the water, they are carried by the stream, and deposited on the flowed land, where they grow and fill the ground in every part; but so incurious are the generality of farmers in this respect, that if the ground is but well covered, they care not what it is, few of them ever taking any pains to weed or clean their pastures.

The method which I propose for the management of these Meadows is, never to flow them till the middle or latter end of March, excepting once or twice in winter, when there may happen floods, which may bring down a great share of soil from the upper lands, at which times it will be of great service to let water upon the Meadows, that the soil may settle there; but the sooner the wet is drained off when this is lodged, the greater advantage the Meadows will receive by it; but from the end of March to the middle of May, in dry seasons, by frequently letting on the water, the growth of the Grass will be greatly encouraged, and at this season there will be no danger of destroying the roots of the Grass; and after the hay is carried off the ground, if the season should prove dry, it will be of great service to the Grass, if the Meadows are flowed again; but when this is practised, no cattle should be turned into the Meadows, till the surface of the ground is become firm enough to bear their weight without poaching the land, for otherwise the Grass will suffer more from the treading of the cattle, than it will receive benefit by the flowing; but these are things which the country people seldom regard, so that the Meadows are generally very unfightly, and rendered less profitable.

I would also recommend the weeding of these Meadows twice a year, the first time in April, and again in October; at which times if the roots of Docks and all bad weeds are cut up with a spaddle, the Meadows will soon be cleared of this trumpery, and the herbage greatly improved.

Another great improvement of these lands might be procured, by rolling them with a heavy roller in spring and autumn. This will press the surface of the ground even, whereby it may be mown much closer, and it will also sweeten the Grass; and this piece of husbandry is of more service to pastures than most people are aware of.

As to those Meadows which cannot be flowed, there should be the same care taken to weed and roll them, as hath been directed for the Water Meadows; as also never to let heavy cattle graze upon them in winter when they are wet; for the cattle will then poach them, and greatly injure the Grass; therefore these should be fed down as close as possible in the autumn, before the heavy rains fall to render the ground soft; and those pastures which are drier, may be kept to supply the want of these in winter; and where there are not cattle enough to eat down the Grass in time, it will be much better to cut off what is left, than to suffer it to rot upon the ground, for that will prevent the Grass from shooting early in the spring; but where people have not cattle enough of their own to eat down the Grass in time, they had much better take in some of their neighbours, than suffer their fog (as it is called) to remain all the winter. When these Meadows are fed in the autumn, the greater variety of animals are turned in, the closer they will eat the Grass; and I am fully convinced, the closer it is eaten, the better the Grass will come up the following spring; therefore, if during the time while the cattle are feeding, the Meadows are well rolled, the animals will eat the Grass much closer than they otherwise would.

Those persons who are best skilled in this part of husbandry, always dress their Meadows every other, or at least every third year, without which it is in vain to expect any good crop of hay; but the generality of the farmers are so much distressed for dressing to supply their Corn land, as not to have any to spare for

M E D

for their Meadows, so that they are content with what the land will naturally produce, rather than take any part of their manure from their arable ground; but this is a very imprudent piece of husbandry; for if land is to be annually mowed for hay, can it be supposed that it will produce a good crop long, unless there are proper dressings allowed it? And when ground is once beggared for want of manure, it will be some years before it can be recovered again; but I shall reserve what is necessary to be farther enlarged on this subject, to be fully treated under the article of PASTURE.

MEADOW SAFFRON. See C OLCHEICUM.

MEDEOLA. Lin. Gen. Plant. 411.

The CHARACTERS are,

The flower has no empalement; it hath six oblong oval petals which are equal, spread open, and turn backward; and six awl-shaped stamina the length of the petal, terminated by incumbent summits, and three corniculated germen terminating the style, crowned by thick recurved stigmas. The germen afterward turns to a roundish trifid berry with three cells, each containing one heart-shaped seed.

This genus of plants is ranged in the third section of Linnæus's sixth class, which includes those plants whose flowers have six stamina and three styles.

The SPECIES are,

1. MEDEOLA (*Asparagoides*) foliis ovato-lanceolatis alternis, caule scandente. *Medeola with oval, spear-shaped, alternate leaves, and a climbing stalk. Asparagus Africanus, scandens, myrti folio. Hort. Piss. 17. Climbing African Asparagus, with a Myrtle leaf.*
2. MEDEOLA (*Angustifolia*) foliis lanceolatis alternis, caule scandente. *Medeola with spear-shaped alternate leaves, and a climbing stalk. Asparagus Africanus, scandens, myrti folio angustiore. Hort. Piss. 17. Climbing African Asparagus, with a narrower Myrtle leaf.*
3. MEDEOLA (*Virginiana*) foliis verticillatis, ramis inermibus. Lin. Sp. Plant. 339. *Medeola with leaves growing in whorls and smooth branches. Lilium five martagon pusillum, floribus minutissimè herbaceis. Pluk. Alm. 410. tab. 328. fol. 4. The Lily or little Martagon, with very small herbaceous flowers.*

The first sort grows naturally at the Cape of Good Hope; this hath a root composed of several dug or oblong knobs, which unite together at the top like that of the Ranunculus, from which arise two or three stiff winding stalks, which divide into branches rising four or five feet high, if they meet with any neighbouring support to which they can fasten, otherwise they will fall to the ground; these are garnished with oval spear-shaped leaves, ending in acute points, placed alternately, and sitting close to the stalks; they are of a light green on their under side, and dark on their upper. The flowers come out from the side of the stalks, sometimes singly, and at others there are two upon a slender short foot-stalk; they have six oblong equal petals which spread open, and are of a dull white colour; within these are ranged six stamina, which are as long as the petals, terminated by incumbent summits. In the center is situated a germen with three horns, sitting upon a short style, crowned by three thick recurved stigmas; the germen afterward turns to a roundish berry with three cells, each containing one heart-shaped seed. It flowers the beginning of winter, and the seeds are ripe in the spring.

The second sort is also a native of the Cape of Good Hope, from whence I received the seeds. This hath a root like the first, but the stalks are not so strong; they climb higher, but do not branch so much; the leaves are much longer and narrower, and are of a grayish colour. The flowers come from the side of the branches, two or three upon each foot-stalk; they are of an herbaceous white colour, shaped like those of the former sort, and appear about the same time, but this has not produced any fruit here. These are undoubtedly distinct species, for they never vary when they are propagated by seeds.

M E D

Both these sorts propagate freely by offsets from the roots, so that when they are once obtained, there will be no necessity of sowing their seeds, which commonly lie a year in the ground, and the plants will not be strong enough to flower in less than two years more, whereas the offsets will flower the following season. The time for transplanting and parting of the roots is in July, when their stalks are entirely decayed, for they begin to shoot toward the end of August, and keep growing all the winter, and decay in the spring. These roots should be planted in pots filled with good kitchen-garden earth, and may remain in the open air till there is danger of frost, when they must be removed into shelter, for they are too tender to live through the winter in the open air; but if they are placed in a warm green-house, they will thrive and flower very well, but they do not produce fruit unless they have some heat in winter; therefore where that is desired, the plants should be placed in a stove kept to a moderate degree of warmth. During the winter, when the plants are in vigour, they should be frequently, but gently watered; but when the stalks begin to decay, they must have very little wet, for much moisture will rot them while they are in an inactive state; during which time, if the pots are placed where they have only the morning sun, they will require little or no water: but when they begin to shoot out their stalks, they should be removed to a warmer situation, and should then be frequently but gently watered.

The flowers of these plants make no great appearance, so the plants are not preserved for their beauty; but as their stalks are climbing, and their leaves are in full vigour in winter, during that season they add to the variety in the green-house.

The third sort is a native of North America; it is by Dr. Linnæus joined to this genus, in which I have followed him; though, if I remember rightly, the characters of this sort do not exactly agree with those of the other, for the flower is either polypetalous, or is cut into many segments, and has but five stamina; it being some years since I saw the flowers, I cannot be very certain if I am right. This hath a small scaly root, from which arises a single stalk about eight inches high, garnished with one whorl of leaves at a small distance from the ground, and at the top there are two leaves standing opposite; between these come out three slender foot-stalks which turn downward, each sustaining one pale herbaceous flower with a purple pointal. It flowers in June, but I have not seen any fruit upon it.

This plant is hardy enough to live in the open air, but does not propagate fast here, as it produces no seeds, so can only be increased by offsets.

MEDICA. Tourn. Inst. R. H. 410. tab. 231. *Medicago. Tourn. Inst. 412. Lin. Gen. Plant. 805.* [This plant takes its name from Media (as Pliny writes) because when Darius Hystaspis carried his army into Greece, he had with him a great many sacks of this seed for provender for his cattle, and so the seeds came to be scattered in Greece.] Medick, or La Lucerne.

The CHARACTERS are,

The flower hath a bell-shaped empalement of one leaf, cut into five equal acute points. The flower is of the butterfly kind; the standard is oval, entire, and the border is reflexed; the two wings are oblong, oval, and fixed by an appendix to the keel; the keel is oblong, bifid, obtuse, and reflexed toward the standard. It has ten stamina, nine of which are joined almost to their tops, the other is single; they are terminated by small summits. It hath an oblong compressed germen which is incurved, sitting on a short style, terminated by a small stigma; this and the stamina are involved by the keel and standard. The germen afterward turns to a compressed moon-shaped pod, inclosing several kidney-shaped seeds.

This genus of plants is ranged in the third section of Linnæus's seventeenth class, which includes the herbs with a butterfly flower, having ten stamina in two houses. He also has joined the Medica and Medicago

M E D

Medicago of Tournefort together, making them one genus under the title *Medicago*, but Tournefort makes the distinguishing character of *Medicago* to consist in having a falcated compressed pod. Therefore I shall here separate those plants whose pods are of that form, from the others whose pods are twisted like a screw; and as the title of *Medica* was first applied to the Lucern, so I shall continue it to those species as have such pods, and refer the others to the genus of *Medicago*.

The SPECIES are,

1. *MEDICA (Sativa)* pedunculis racemosis, leguminibus contortis, caule erecto glabro. Lin. Sp. 1096. *Medick with branching foot-stalks, contorted pods, and an erect smooth stalk.* *Medica major, erectior, floribus purpurascens.* J. B. 2. 382. *Greater upright Medick with purplish flowers, commonly called La Lucerne, and by the French, Burgundy Hay.*
2. *MEDICA (Falcata)* pedunculis racemosis, leguminibus lunatis, caule prostrato. Flor. Suec. 620. *Medick with branching foot-stalks, moon-shaped pods, and trailing stalks.* *Medica sylvestris, floribus croceis.* J. B. 2. 383. *Wild Medick with Saffron-coloured flowers.*
3. *MEDICA (Radiata)* leguminibus reniformibus, margine dentatis, foliis ternatis. Hort. Cliff. 377. *Medick with kidney-shaped pods indented on the borders, and trifoliate leaves.* *Medicago annua, trifolii facie.* Tourn. Inst. R. H. 412. *Annual Medicago with the appearance of Trefoil.*
4. *MEDICA (Hispanica)* caule herbaceo procumbente, foliis pinnatis, leguminibus ciliato-dentatis. *Medick with a trailing herbaceous stalk, winged leaves, and pods having hairy indentures.* *Medicago vulnerariæ facie Hispanica.* Tourn. Inst. R. H. 412. *Spanish Medicago with the appearance of Ladies Finger.*
5. *MEDICA (Italica)* caule herbaceo prostrato, foliis ternatis, foliolis cuneiformibus supernè serratis, leguminibus margine integerrimis. *Medick with a prostrate herbaceous stalk, trifoliate leaves whose lobes are wedge-shaped and sawed at the top, and the borders of the pods entire.* *Medicago Italica, annua maritima, trifolia, polycarpus, fructu toroso non spinoso.* Mitchel. Hort. Piss. *Annual, Italian, maritime Medicago with trifoliate leaves, and bearing much fruit, which is thick and without spines.*
6. *MEDICA (Cretica)* caule herbaceo prostrato, foliis radicalibus integerrimis, caulinis pinnatis leguminibus dentatis. *Medick with a prostrate herbaceous stalk, the bottom leaves entire, those on the stalks winged, and indented pods.* *Medicago vulnerariæ facie Cretica.* Tourn. Inst. 412. *Cretan Medicago, with the appearance of Ladies Finger.*
7. *MEDICA (Arborea)* leguminibus lunatis margine integerrimis caule arborco. Hort. Cliff. 376. *Medick with moon-shaped pods whose borders are entire, and a tree-like stalk.* *Medicago trifolia, frutescens, incana.* Tourn. Inst. R. H. 412. *Shrubby, hoary, three-leaved Medica, or the Cytisus Virgilii.*

The first sort hath a perennial root and annual stalks, which rises near three feet high in good land; these are garnished with trifoliate leaves at each joint, whose lobes are spear-shaped, about an inch and a half long, and half an inch broad, a little sawed toward their top, of a deep green, and placed alternately on the stalks. The flowers grow in spikes, which are from two to near three inches in length, standing upon naked foot-stalks which are two inches long, rising from the wings of the stalk; they are of a Pea bloom or butterfly kind, of a fine purple colour, and are succeeded by compressed moon-shaped pods, which contain several kidney-shaped seeds. It flowers in June, and the seeds ripen in September.

There are the following varieties of this plant:

One with Violet-coloured flowers.

Another with pale blue flowers.

And a third with variegated flowers.

These variations of their flowers have accidentally risen from seed, therefore are not to be supposed different plants; yet those with the pale blue and variegated flowers are never so strong as those with purple, so are less profitable to the cultivators.

M E D

This plant is supposed to have been brought originally from Media, and from thence had its name *Medica*: it is by the Spaniards called *Alfafa*; by the French, *La Lucerne*, and *Grand Trefle*; and by several botanic writers it is called *Fœnum Burgundicum*, i. e. *Burgundian Hay*. But there is little room to doubt of this being the *Medica* of Virgil, Columella, Palladius, and other ancient writers of husbandry, who have not been wanting to extol the goodness of this fodder, and have given direction for the cultivation of it in those countries where they lived.

But notwithstanding it was so much commended by the antients, and hath been cultivated to so good purpose by our neighbours in France and Switzerland for many years, it hath not as yet found so good reception in our country as could be wished; nor is it cultivated in considerable quantities, though it is evident, it will succeed as well in England as in either of the before-mentioned countries, though will not bear cutting so often here, yet is extremely hardy, and resists the severest cold of our climate: as a proof of this, I must beg leave to mention, that the seeds which have happened to be scattered upon the ground in autumn, have come up, and the plants have endured the cold of a severe winter, and made very strong plants the following season.

About the year 1650, the seeds of this plant were brought over from France, and sown in England; but whether for want of skill in its culture, whereby it did not succeed, or that the people were so fond of going on in their old beaten road, as not to try the experiment whether it would succeed here or not, was the occasion of its being entirely neglected in England, I cannot say, but it is very certain that it was neglected many years, so as to be almost forgotten. However, I hope, before I quit this article, to give such directions for its culture, as will encourage the people of England to make farther trial of this valuable plant, which grows in the greatest heat, and also in very cold countries, with this difference only, that in very hot countries, such as the Spanish West-Indies, &c. where it is the chief fodder for their cattle at this time, they cut it every week; whereas in cold countries, it is seldom cut oftener than four or five times in a year. And it is very likely that this plant may be of great service to the inhabitants of Barbadoes, Jamaica, and the other hot islands in the West-Indies, where one of the greatest things they want is fodder for their cattle; since by the account given of this plant by Pere Feuillé, it thrives exceedingly in the Spanish West-Indies, particularly about Lima, where they cut it every week, and bring it into the market to sell, and is there the only fodder cultivated.

It is also very common in Languedoc, Provence, and Dauphiné, and all over the banks of the Rhone, where it produces abundantly, and may be mowed five or six times in a year. Horses, mules, oxen, and other domestic cattle, love it exceedingly; but above all when it is green, if they are permitted to feed on it, and especially the black cattle, which will feed very kindly upon the dried plant; the excess of which is, by many people, thought to be very dangerous; but it is said to be exceeding good for milch cattle, to promote their quantity of milk; and is also said to agree with horses the best of all, though sheep, goats, and most other cattle, will feed upon it, especially when young.

The directions given by all those who have written of this plant are very imperfect, and generally such as, if practised in this country, will be found entirely wrong; for many of them order the mixing of this seed with Oats or Barley, (as is practised for Clover) but in this way it seldom comes up well, and if it does, it will draw up so weak by growing amongst the Corn, as not to be recovered under a whole year, if ever it can be brought to its usual strength again. Others have directed it to be sown upon a low, rich, moist soil, which is found to be the worst next to a clay

M E D

clay, of any for this plant; in both which the roots will rot in winter, and in a year or two the whole crop will be destroyed.

But the soil in which this plant is found to succeed best in this country is, a light, dry, loose, sandy land, which should be well ploughed and dressed, and the roots of all noxious weeds, such as Couch Grass, &c. destroyed, otherwise they will overgrow the plants while young, and prevent their progress.

The best time to sow the seed is about the middle of April, when the weather is settled and fair; for if you sow it when the ground is very wet, or in a rainy season, the seeds will burst and come to little (as is often the case with several sorts of the leguminous plants;) therefore you should always observe to sow it in a dry season, and if there happens rain in about a week or ten days after it is sown, the plants will soon appear above ground.

But the method I would direct for the sowing these seeds is as follows: after having well ploughed and harrowed the land very fine, you should make a drill quite across the ground, about half an inch deep, into which the seeds should be scattered very thin by a hopper fixed to a drill plough; then cover them over half an inch thick, with the earth that came out of the drill; then proceed to make another drill about two feet and a half from the former, sowing the seeds therein in the same manner as before, and so proceed through the whole spot of ground, allowing the same distance between row and row, and scatter the seeds very thin in the drills. In this manner, an acre of land will require about six pounds of seeds; for when it is sown thicker, if the seed grows well, the plants will be so close as to spoil each other in a year or two, the heads of them growing to a considerable size, as will also the roots, provided they have room. I have measured the crown of one root, which was in my possession, eighteen inches diameter; from which I cut near four hundred shoots at one time, which is an extraordinary increase, and this upon a poor, dry, gravelly soil, which had not been dunged for many years, but the root was at least fourteen years old; so that if this crop be well cultivated, it will continue many years, and be equally good as when it was first sown; for the roots generally run down very deep in the ground, provided the soil be dry; and although they should meet a hard gravel a foot below the surface, yet their roots would penetrate it, and make their way downward, as I have experienced, having taken up some of them which were above four feet in length, and had run above two feet into a rock of gravel, which was so hard as not to be loosened without mattocks and crows of iron, and that with much difficulty.

The reason for directing this seed to be sown in rows is, that the plants may have room to grow; and for the better stirring the ground between them, to destroy the weeds, and encourage the growth of the plants, which may be very easily effected with a Dutch hoe, just after the cutting the crop each time, which will cause the plants to shoot again in a very little time, and be much stronger than in such places where the ground cannot be stirred; but when the plants first come up, the ground between them should be hoed by hand with a common hoe; and if in doing of this you cut up the plants where they are too close in the rows, it will cause the remaining to be much stronger. This hoeing should be repeated two or three times while the plants are young, according as the weeds are produced, observing always to do it in dry weather, that the weeds may the better be destroyed; for if it be done in moist weather, they will take root and grow again.

With this management, the plants will grow to the height of two feet, or more, by the beginning of August, when the flowers will begin to appear, when it should be cut for the first time, observing to do it in a dry season, especially if it is to be made into hay, and keep it often turned, that it may soon dry, and be carried off the ground; for if it lie long upon the roots, it will prevent their shooting again. After the

M E D

crop is taken off, you should stir the ground between the rows with a hoe, to kill the weeds, and loosen the surface, which will cause the plants to shoot again in a short time, so that by the middle of September there will be shoots four or five inches high, when you may turn in sheep upon it to feed it down, for it will not be fit to cut again the same season; nor should the shoots be suffered to remain upon the plants, which would decay when the frosty weather comes on, and fall down upon the roots, and prevent their shooting early the succeeding spring; but these sheep should not remain so long upon it as to endanger the crowns of the roots.

So that the best way is to feed it until November, when it will have done shooting for that season; but it should not be fed by large cattle the first year, because the roots being young, would be in danger of being destroyed, either by their trampling upon them, or their pulling them out of the ground; but sheep will be of service to the roots by dunging the ground, provided they do not eat it too close.

The beginning of February, the ground between the roots should be again stirred with the hoe, to encourage them to shoot again; but in doing of this you should be careful not to injure the crown of the roots, upon which the buds are at that time very turgid, and ready to push. With this management, if the soil be warm, by the middle of March the shoots will be five or six inches high, when, if you are in want of fodder, you may feed it down till a week in April; after which it should be suffered to grow for a crop, which will be fit to cut the beginning of June, when you should observe to get it off the ground as soon as possible, and stir the ground again with a Dutch hoe, which will forward the plants shooting again, so that by the middle of July, there will be another crop fit to cut, which must be managed as before: after which it should be fed down again in autumn; and as the roots by this time will have taken deep hold in the ground, there will be little danger of hurting them, if you should turn in larger cattle; but you must always observe not to suffer them to remain after the roots have done shooting, lest they should eat down the crown of the roots below the buds, which would considerably damage, if not destroy them. In this manner you may continue constantly to have two crops to cut, and two feedings upon this plant, and in good summers there may be three crops cut, and two feedings; which will be a great improvement, especially as this plant will grow upon dry barren soils, where Grass will produce little, especially in dry seasons, when it will be of great use, the Grass being often burnt up. And as it is an early plant in the spring, so it will be of great service when fodder falls short at that season, when it will be fit to feed at least a month before Grass or Clover; for I have had this plant eight inches high by the tenth of March, old style, at which time the Grass in the same place has scarcely been one inch high.

That the cold will not injure this plant, I am fully satisfied; for in the very cold winter, anno 1729-30, I had some roots of this plant which were dug up in October, and laid upon the ground in the open air till the beginning of March, when I planted them again, and they shot out very vigorously soon after; nay, even while they lay upon the ground, they struck out fibres from the under side of the roots, and begun to make shoots from the crown of the roots. But that wet will destroy the roots I am fully convinced, for I sowed above an acre upon a moist spot of ground for a trial, which came up very well, and flourished exceedingly during the summer season, but in winter, when the great rains fell, the roots began to rot at bottom, and before the spring most of them were destroyed. There has been lately some persons who have advised the sowing of Lucern in broad-cast, and to make use of a strong harrow, to tear up and destroy the weeds which naturally grow up among the plants; but this advice has been given too prematurely, therefore it is to be hoped will not be followed by any discreet persons, who are desired to take

M E D

a survey of some of these lands which have been so cultivated three or four years, which I am fully persuaded will convince them of the bad husbandry, for no person who has any regard to neatness and utility, will ever practise this method.

The best places to procure the seed from, are Switzerland, and the northern parts of France, for the seeds sowed in those countries succeed better with us than that which comes from a more southern climate; but this seed may be sowed full as well in England, and in as great plenty, were people curious enough to let the first crop stand for that purpose; in order to which, a small quantity of the plants should be suffered to grow uncut till the seeds are ripe, which is commonly about the beginning of September, when it must be cut, and laid to dry in an open barn, where the air may freely pass through, but be defended from the wet; for if it be exposed thereto, it will shoot while it remains in the pod, whereby it will be spoiled. When it is quite dry, it must be threshed out, and cleansed from the husk, and preserved in a dry place till the season for sowing it; and this seed sowed in England is much preferable to any brought from abroad, as I have several times experienced, the plants produced from it having been much stronger than those produced from French, Helvetian, and Turkey seeds, which were sown at the same time, and on the same soil and situation.

I am inclinable to think, that the reason of this plant not succeeding, when it has been sown in England, has either been occasioned by the sowing it with Corn, with which it will by no means thrive (for though the plant be very hardy when grown pretty large, yet at its first coming up, if it be incommoded by any other plants or weeds, it seldom does well; therefore it should always be sown by itself, and carefully cleared from weeds until it has strength, after which it is not easily destroyed;) or, perhaps, people have sown it at a wrong season, or in wet weather, whereby the seeds have rotted, and never come up, which hath discouraged their attempting it again: but however the success has been, I dare aver, that if the method of sowing and managing of this plant, which is here laid down, be duly followed, it will be found to thrive as well as any other sort of plant now cultivated in England, producing a much greater crop than any other sort of fodder, and will continue much longer; for if the ground be duly stirred after the cutting each crop, and the last crop fed as hath been directed, the plants will continue in vigour forty years or more, without renewing, provided they are not permitted to seed, which will weaken the roots more than four times cutting it would do. The hay of this plant should be kept in close barns, it being too tender to be kept in ricks open to the air as other hay; but it will remain good, if well dried before it be carried in, three years. The people abroad reckon an acre of this fodder sufficient to keep three horses all the year round.

And I have been assured by persons of undoubted credit, who have cultivated this plant in England, that three acres of it have fed ten cart-horses from the end of April to the beginning of October, without any other food, though they have been constantly worked. Indeed, the best use which can be made of this Grass is, to cut it, and give it green to the cattle; where this hath been daily practised, I have observed that by the time the field has been cut over, that part which was the first cut hath been ready to cut again; so that there has been a constant supply in the same field, from the middle of April to the end of October: when the season has continued long mild, and when the summers have proved showery, I have known six crops cut in one season, but in the driest seasons there will be always three or four. When the plant begins to flower, it should then be cut; for if it stands longer, the stalks will grow hard, and the under leaves will decay, so that the cattle will not so greedily devour it. Where there is a quantity of this cultivated, some of it should be cut before the

M E D

flowers appear, otherwise there will be too much to cut within a proper time.

When this is made into hay, it will require a great deal of making; for as the stalks are very succulent, it must be often turned, and exposed a fortnight or longer, before it will be fit to house; for this requires a longer time to make than Saint Foin; therefore, when it is cut, it should be carried to make upon some Grass ground, because the earth in the intervals of the rows will wash up, and mix with the hay in every shower of rain, and by carrying it off as soon as it is cut, the plants will shoot up again soon; but it is not so profitable for hay, as to cut green for all sorts of cattle, but especially horses, which are extremely fond of it; and to them it will answer the purpose both of hay and Corn, and they may be worked at the same time just as much as when they are fed with Corn, or dry food.

The second sort grows naturally in the south of France, in Spain, Italy, and also in some more northern countries, and has been supposed only a variety of the first, but I have frequently cultivated this by seeds, and have never observed it to alter. The stalks of this are smaller, and never rise so high, generally prostrating on the ground; the leaves are not half so broad, the flowers are produced in short roundish spikes, and are of a Saffron colour. This flowers about the same time as the first, and the seeds ripen the latter part of summer. It may be easily propagated by seeds, and hath a perennial root which will continue many years, but is seldom cultivated any where. The third sort grows naturally in Italy; this is an annual plant, having several slender branching stalks a foot and a half long, which spread on the ground, garnished with trifoliate leaves, whose lobes are oval, spear-shaped, and entire. The flowers are produced singly upon slender foot-stalks, which proceed from the side of the branches; they are small, of a yellow colour, and shaped like those of the former sort; these are succeeded by broad, flat, moon-shaped pods, whose borders are indented, and these indentures are terminated by fine hairs; in each of these pods is lodged four or five kidney-shaped seeds. It flowers in June and July, and the seeds ripen in the autumn.

The fourth sort grows naturally in Spain; this is also an annual plant, whose stalks grow a foot and a half long, trailing on the ground, and are garnished with winged leaves composed of two pair of small lobes, terminated by one large, oval, spear-shaped lobe, which are a little hoary, and placed alternately at the joints. The flowers stand upon long slender foot-stalks, each sustaining four or five gold-coloured flowers at the top, which are succeeded by compressed moon-shaped pods, not half so large as those of the third sort, but have hairy indentures like those. This flowers and perfects its seeds about the same time as the former.

The fifth sort grows naturally on the borders of the sea in several parts of Italy; it is also an annual plant, with prostrate herbaceous stalks about a foot long, garnished with trifoliate leaves, whose lobes are wedge-shaped and sawed toward the top. The flowers are produced upon slender foot-stalks arising from the joints of the stalk; they are about an inch long, each sustaining five or six pale yellow flowers, which are succeeded by small, thick, moon-shaped pods, whose borders are entire, containing three or four small kidney-shaped seeds in each. It flowers and seeds about the same time with the two former.

The sixth sort grows naturally in the Archipelago; this is an annual plant, from whose roots come out several oblong leaves about two inches and a half long, narrow at their base, but broad toward the top, where they are rounded; these spread on the ground, and between them come out the stalks which are slender, about a foot long, branching out into smaller, garnished with winged hoary leaves: those on the lower part of the stalk are composed of two pair of lobes terminated by an odd one; these are equal in size,

size, but those on the upper part of the stalks are trifoliate. The flowers are produced at the end of the stalks; they are small, yellow, and shaped like those of the other sorts, and are succeeded by compressed moon-shaped pods, which are acutely indented on their borders, and contain three or four kidney-shaped seeds. This plant flowers and ripens its seeds about the same time as the other.

These annual sorts are preserved in the gardens of those who are curious in botany; the seeds of these should be sown upon an open bed of fresh ground, in the places where the plants are to remain, because they do not bear transplanting well, unless when they are very young. As the plants spread their branches on the ground, so they should not be sown nearer than two feet and a half asunder; when the plants come up, they will require no other care but to keep them clean from weeds. In June they will begin to flower, and as the stalks and branches extend, there will be a succession of flowers produced till the autumn; but the early flowers are such as will have good seeds succeed them; for those which come late in summer, have not time to ripen before the cold weather comes on.

The seventh sort grows naturally in the islands of the Archipelago, in Sicily, and the warmest parts of Italy. This rises with a shrubby stalk to the height of eight or ten feet, covered with a gray bark, and divides into many branches, which, while young, are covered with a hoary down; these are garnished at each joint with trifoliate leaves, standing upon foot-stalks about an inch long; there are two or three of these at each joint, so that the branches are closely covered with them; the lobes are small, spear-shaped, and hoary on their under side; these remain all the year. The flowers are produced on foot-stalks which arise from the side of the branches, they are of a bright yellow, each foot-stalk sustaining four or five flowers; these are succeeded by compressed moon-shaped pods, each containing three or four kidney-shaped seeds.

It flowers great part of the year, and when the winters are favourable all the year; or when the plants are sheltered in winter, they are seldom destitute of flowers; but those in the open air begin to flower in April, and continue in succession till December. Those flowers which appear early in summer will have their seeds ripe in August, or the beginning of September, and the others will ripen in succession till the cold stops them.

This plant may be propagated by sowing the seeds upon a moderate hot-bed, or a warm border of light earth, in the beginning of April; and when the plants come up, they should be carefully cleared from weeds, but they should remain undisturbed, if sown in the common ground, till September following; but if on a hot-bed, they should be transplanted about Midsummer into pots, placing them in the shade until they have taken root; after which they may be removed into a situation where they may be screened from strong winds, in which they may abide till the latter end of October, when they must be put into a common garden frame, to shelter them from hard frosts; for those plants which have been brought up tenderly, will be liable to suffer by hard weather, especially while they are young. In April following these plants may be shaken out of the pots, and placed in the full ground where they are designed to remain, which should be in a light soil and a warm situation, in which they will endure the cold of our ordinary winters extremely well, and continue to produce flowers most part of the year, and retaining their leaves all the winter renders them the more valuable.

Those also which were sown in an open border may be transplanted in August following, in the same manner; but in doing of this you must be careful to take them up with a ball of earth to their roots, if possible, as also to water and shade them until they have taken root; after which they will require little more care than to keep them clean from weeds, and to prune off the luxuriant branches to keep them with-

in due compass; but you should never prune them early in the spring, nor late in autumn, for if frost should happen soon after they are pruned, it will destroy the tender branches, and many times the whole plant is lost thereby.

These plants have been constantly preserved in the green-house, supposing them too tender to live thro' the winter in the open air; but I have had large plants of this kind, which have remained in a warm situation many years without any cover, and have been much stronger, and flowered better, than those which were housed; though, indeed, it will be proper to keep a plant or two in shelter, lest by a very severe winter (which sometimes happens in England) the plants abroad should be destroyed.

They may also be propagated by cuttings, which should be planted in April, upon a bed of light earth, and watered and shaded until they have taken root, after which they may be exposed to the open air; but they should remain in the same bed till July or August following, before they are transplanted, by which time they will have made strong roots, and may be removed with safety to the places where they are to remain, observing (as was before directed) to water and shade them until they have taken root; after which you may train them up with strait stems, by fastening them to sticks, otherwise they are apt to grow crooked and irregular; and when you have got their stems to the height you design them, they may then be reduced to regular heads, and with pruning their irregular shoots every year, they may be kept in very good order.

This plant grows in great plenty in the kingdom of Naples, where the goats feed upon it, with whose milk the inhabitants make great quantities of cheese; it also grows in the islands of the Archipelago, where the Turks use the wood of these shrubs to make handles for their sabres, and the Calioyers of Patmos make their beds of this wood.

This is, as hath been before observed, by many people, supposed to be the *Cytisus* of Virgil, *Columella*, and the old writers in husbandry, which they mention as an extraordinary plant, and worthy of cultivation for fodder, from whence several persons have recommended it as worthy of our care in England. But however useful this plant may be in Crete, Sicily, Naples, or those warmer countries, yet I am persuaded it will never thrive in England, so as to be of any real advantage for that purpose; for in severe frost it is very subject to be destroyed, or at least so much damaged, as not to recover its former verdure before the middle or latter end of May; and the shoots which are produced will not bear cutting above once in a summer, and then will not be of any considerable length; and the stems growing very woody, will render the cutting of it very troublesome; so that, upon the whole, it can never answer the trouble and expence in cultivating it, nor is it worth the trial, since we have so many other plants preferable to it; though in hot, dry, rocky countries, where few other plants will thrive, this may be cultivated to great advantage, since in such situations this plant will live many years, and thrive very well.

But however unfit this may be for such uses in England, yet for the beauty of its hoary leaves, which will abide all the year, together with its long continuance in flower, it deserves a place in every good garden, where, being intermixed with shrubs of the same growth, it makes a very agreeable variety.

As there are at present so many persons inquisitive to know which is the true *Cytisus* mentioned by the ancients, I have taken the pains of transcribing briefly what they have said as to its description, by which may be judged how uncertain it is to determine in an affair where there is so little to be found in authors to assist us.

Theophrastus says, *Cytisus* is such an enemy to other plants, that it will kill them, by robbing them of nourishment, and that the medulla of it is so hard and thick, that it comes the nearest of any thing to *Ebenum*.

The

M E D

The shrub *Cytisus*, by Aristomachus, the Athenian, as may be seen in Pliny [who says much the same as Varro and Columella, from whom probably he has taken it,] is highly commended for food for sheep, and, being dry, for swine; the utility [as to health and fattening, Dal.] the same as that of *Ervum*, but the satiety is quicker, a four-footed animal growing fat with a little of it, so that cattle set light by their Barley.

No food makes a greater quantity, nor better milk, and it excels all things as to the diseases of cattle; moreover, being given dry, or in a decoction of water mixed with wine, to nurses whose milk fails, it helps very much, and makes the children stronger, and take to their feet sooner; green, it is also good for them, or dry, if it be made moist.

Democritus and Aristomachus say, bees will never want food, if they have *Cytisus* enough, nor is any thing cheaper.

If, when the seed be sown, showers are wanting, Columella directs, That it be watered the fifteen following days.

It is sown [according to the antients] after the equinoxes. It is perfected in three years. It is mown in the vernal equinox [for it flourishes all the winter, Dal.] with the cheap labour of a boy, or old woman.

The *Cytisus* is hoary in aspect. If any one would express its likeness briefly, it is a shrub of a broader sort of Trefoil.

In winter, being moistened, ten pounds will satisfy a horse, and a less quantity other animals. Being dry, it has more virtue, and a less quantity satisfies.

This shrub was found in the isle Cythnus, thence it was translated into all the Cyclades, and afterwards into the cities of Greece, where it occasioned a great increase of cheese.

It fears not the injury of heat nor cold, nor hail nor snow, and Hyginus adds, nor of enemies, because the wood is of no value.

Also Galen, in his book de Antid. writes, "*Cytisus* is a shrub. In Mysia, in that part that is nearest to our province, there is a tract which they call Brotton, in which there is a place full of *Cytisus*, from the flowers of which, all agree, the bees make very much honey.

"It is a fruticose plant; it rises to the height of a Myrtle."

He says, seven simple leaves have the faculty of digesting, mixed with warm water, as the leaves of Mallows: thus Galen.

Cornarus too securely writes, That *Cytisus* either never came among the Germans, or that it perished long ago. From what Pliny says, That it was very rare in Italy in his time, he cannot persuade me, that nothing could grow in Germany, that was scarce in Italy. Jo. Bauh.

Strabo, contrary to Dioscorides, Pliny, and Galen, will have the *Cytisus* to be a tree, and he likens it to the Balsamum, an odoriferous tree, which probably was the occasion, that Cornarus thought this tree came nearest to a shrub, because Pliny said the wood was of no value, therefore he persuades himself, that it produces woody branches, not tender and soft, as in an herb.

But Virgil shews it is neither a tree nor a shrub, when he says:

- " — Non me pascente, capellæ,
 " Florentem *Cytisum*, & salices capretis amaras."
 [Buc. Eclog. 1.
 " Sic *Cytiso* pastæ distendunt ubera vaccæ."
 Eclog. 9.
 " Nec *Cytiso* saturantur apes, nec fronde capellæ."
 Eclog. 10.

Virgil, I say, indicates very plainly in these verses, that it is neither a tree nor a shrub, for goats do not use it; nor can they, if they were wont to eat flowery trees. Neither will what Cornarus says avail, when

M E D

Pliny says the wood is of no value, that it must of necessity produce woody branches; nay, the contrary is rather true, that there is no value in the wood, that it bears viny pliable branches, with which the goats cannot be satiated.

Theocritus very plainly expresses it, That *Cytisus* is a very grateful food to goats:

Ἡ αἶξ τὸν κύτισον, ὀλίγον τὴν αἶγαν δώκει.

"Capra *Cytisum*, lupus capellam sequitur."

Which is thus imitated by Virgil:

"Torva leana lupum sequitur, lupus ipse capellam:
 "Florentem *Cytisum* sequitur lasciva capella."

Amatus, to avoid this difficulty, concludes *Cytisus* to be between trees and shrubs, by the difference of genus, to be distinguished by Pliny, that, as a tree, it may be used in the feminine gender, as a shrub in the masculine, which is not worth the minding.

Columella uses *Cytisus* in the feminine gender, and Theocritus and others in the masculine; as Cob. Const. in Lex. who writes that it was called ἀρνίφυλλον, and Theocritus calls this shrub κύσιλον, and others, κύτισον; others again τῆλις.

Of Cythnus, or, as others, of Cythusa, the name of an island, as Severius has it.

Among these words of Dioscorides in some manuscripts, there are found, falsely written, in some, Tellenen Triphyllon, in others Lotum Grandem.

Dioscorides's description of the *Cytisus* is not so accurate, that from it the true *Cytisus* may be ascertained.

Although in the several species of *Cytisuses* it is hard to judge which is the legitimate *Cytisus* specified by the antients; the most skilful take it to be that which Maranthus has described, which is our *Medica*, which has been ranged under the genus of *Cytisus*, by most of the writers before Dr. Tournefort, who established the genus of *Medicago*, on account of the seed-vessel being like that of *Medica*, or Snail Trefoil.

This plant grows in great plenty at Abruzzo, where the goats feed upon it, and from their milk are made great quantities of cheese. I have had both seeds and specimens of the plant sent me from thence, by persons of the greatest skill in botany, who have assured me, that this plant is generally supposed, by all the people of learning in that country, to be the plant mentioned by Virgil.

Trifolium fruticans, according to Dodonæus, or Polemonium, according to some, is improperly called, *Cytisus* by many.

Trifolium candidum Dodon. by some is said to be the *Cytisus* of Columella, concerning which, see Lib. Hist. n. 9. 17. of Trifolious herbs.

Tragus writes, That their opinion is to be rejected, who interpret the *Trifolium pratense* to be a *Cytisus*. Some contend the *Trifolium candidum* of Dodon. the Rectum Melilotum vulgare, to be the *Cytisus* of the antients, as Dodonæus says, but they have not hit on the truth.

Ruellius writes, That he was afraid that Marcellus took *Cytisus* for *Medica*.

MEDICAGO. Lin. Gen. Plant. 805. *Medica*. Tourn. Inst. R. H. 410. tab. 231. Snail Trefoil.

The CHARACTERS are,

The flower hath a cylindrical erect empalement of one leaf, which is cut at the brim into five equal acute segments. The flower is of the butterfly kind, having an oval erect standard, whose borders are reflexed. The wings are oblong, oval, and fixed to the keel by an appendix. The keel is oblong, bifid, obtuse, and reflexed. It hath ten stamens, nine of which are joined, and the other is single, terminated by small summits, and an oblong germen, which sits upon a short style, is involved with the stamens by the keel, and crowned by a very small stigma. The germen afterward turns to a long compressed pod, twisted into the form of a snail, inclosing many kidney-shaped seeds.

This

This genus of plants is ranged in the same section and class, as the former by Tournefort and Linnæus.

The SPECIES are,

1. **MEDICAGO** (*Marina*) pedunculis racemosis, leguminibus cochleatis, spinosis, caule procumbente tomentoso. Hort. Cliff. 378. *Medicago with branching foot-stalks, snail-shaped prickly pods, and a trailing woolly stalk.* Medica Marina. Lob. Icon. 38. *Sea Medick, or Snail Trefoil.*
 2. **MEDICAGO** (*Scutellata*) leguminibus cochleatis, inermibus stipulis dentatis caule anguloso diffuso, foliolis oblongo ovatis acute dentatis. *Medicago with smooth snail-shaped pods, indented stipule, an angular diffused stalk, and oblong, oval, small leaves, which are sharply indented.* Medica scutellata. J. B. 2. 384. *Snail Trefoil, commonly called Snails.*
 3. **MEDICAGO** (*Tornata*) leguminibus tornatis inermibus, stipulis acutè dentatis foliolis serratis. *Medicago with a turned smooth pod, acute indented stipule, and the small leaves sawed.* Medica tornata minor lenis. Park. Theat. 1116. *Snail Trefoil with a smaller, turned, smooth fruit.*
 4. **MEDICAGO** (*Intertexta*) leguminibus cochleatis spinosissimis aculeis utrinque tendentibus. *Medicago with very prickly snail-shaped pods, whose spines point every way.* Medica magno fructu, aculeis sursum & deorsum tendentibus. Tourn. Inst. R. H. 411. *Snail Trefoil with a large fruit, whose spines point upward and downward, commonly called Hedgehog.*
 5. **MEDICAGO** (*Laciniata*) leguminibus cochleatis spinosis, foliolis acutè dentatis tricuspidisque. *Medicago with prickly snail-shaped pods, whose lobes are acutely indented, and terminate in three points.* Medica cochleata dicarpos capsulâ rotundâ spinosâ, foliis eleganter dissectis. H. L. B. *Snail-shaped Trefoil, having a double fruit with a round prickly capsule, and elegant cut leaves.*
- There are many other species of this genus, which grow naturally in the warm parts of Europe, and are frequently preserved in botanic gardens for the sake of variety; but these are rarely cultivated in other gardens, so it would be beside my purpose to enumerate them here.

The first sort grows naturally on the borders of the Mediterranean Sea; this is a perennial plant, with trailing woolly branches about a foot long, which are divided into small branches, garnished with small, trifoliate, downy leaves at each joint, standing upon short foot-stalks. The flowers are produced from the side and at the ends of the branches, in small clusters; they are of a bright yellow colour, and are succeeded by small roundish snail-shaped fruit, which are downy, and armed with a few short spines. The flowers appear in June and July, and the seeds ripen in September.

This plant is propagated by seeds, which should be sown upon a warm border of dry soil in the spring, where the plants are designed to remain; when the plants are come up, two or three of them may be transplanted into small pots to be sheltered in winter, because in very severe frost, those which are in the open air are frequently destroyed; though they will endure the cold of our ordinary winters, if they are growing in a dry soil and a sheltered situation. Those plants which are left remaining, will require no other culture but to thin them where they are too close, and keep them clean from weeds. This sort may be propagated by cuttings, which may be planted in June or July, in a shady border, covering them close with a glass to exclude the external air; these will take root in about six weeks time, and may then be either planted in a warm border or in pots, and treated in the same way as the seedling plants.

The second sort is an annual plant, which grows naturally in the warm parts of Europe, but in England it is frequently cultivated in gardens for the oddness of its fruit, which is twisted in the form of a snail; and as it ripens turns to a dark brown colour, so as to have the appearance of snails feeding on the plants at a distant view. This hath trailing branches; the flowers are of a pale yellow, and come out from the

side of the branches. These appear in June and July, and the seeds ripen in the autumn. It is propagated by seeds, which should be sown in the middle of April, where the plants are to remain; and the plants should be thinned where they are too close, and kept clean from weeds, which is all the culture they require.

The third sort is also an annual plant, which grows in the same countries as the former. This hath trailing branches, and yellow flowers like the second sort, but the fruit is much longer and closer twisted, so as to resemble the figure of a vessel called a pipe, being less at each end than in the middle. This is frequently kept in gardens for the sake of variety, and may be propagated and treated in the same way as the second sort.

The fourth sort is an annual plant, which was formerly more cultivated in the English gardens than at present. The stalks, leaves, and flowers, are like those of the two former sorts, but the fruit is much larger, and closely armed with long spines like a hedgehog, from whence it had the title; these spines point every way, so that it is difficult to handle the fruit without smarting for it. This is propagated by seeds in the same way as the second sort, and the plants require the same treatment. It flowers in June, and the seeds ripen in September.

The fifth sort grows naturally in Syria; it is an annual plant, with trailing stalks like the former; the lobes of the trifoliate leaves are wedge-shaped, sharply indented on the edges, and at the top have three acute points. The flowers are of a pale yellow, and the fruit is snail-shaped, but small, armed with many weak spines. It flowers about the same time with the former, and may be cultivated in the same way.

MEDLAR. See **MESPILUS.**

MELAMPYRUM. Tourn. Inst. R. H. 173. tab. 78. Lin. Gen. Plant. 660. *Μελάμυρον*, of *μίλας*, black, and *πυρός*, Wheat.] Cow Wheat.

The CHARACTERS are,

The flower has a permanent empalement of one leaf, which is tubulous, cut into four segments at the brim. The flower is of the lip kind, having an oblong recurved tube compressed at the brim; the upper lip is formed like a helmet, and is compressed and indented at the top; the under lip is plain, erect, and cut into three segments at the top, which are equal and obtuse. It hath four awl-shaped stamina which are curved under the upper lip, two of which are shorter than the other, terminated by oblong summits, and in the center is situated an acute-pointed germen, supporting a single style crowned by an obtuse stigma. The empalement afterward turns to an oblong acute-pointed capsule with two cells, inclosing two pretty large oval seeds.

This genus of plants is ranged in the second section of Linnæus's fourteenth class, which contains those plants whose flowers have two long and two shorter stamina, and the seeds are included in a capsule.

The SPECIES are,

1. **MELAMPYRUM** (*Pratense*) floribus secundis lateralibus, conjugationibus remotis, corollis clausis. Flor. Succ. 513. *Cow Wheat with fruitful foot-stalks of flowers standing at a distance, and the petals shut.* Melampyrum luteum latifolium. C. B. P. 234. *Broad-leaved yellow Cow Wheat.*
2. **MELAMPYRUM** (*Cristatum*) spicis quadrangularibus bracteis cordatis compactis denticulis imbricatis. Flor. Succ. 510. *Cow Wheat with quadrangular spikes, and heart-shaped bractes, which are imbricated.* Melampyrum luteum angustifolium. C. B. P. 234. *Yellow narrow-leaved Cow Wheat.*
3. **MELAMPYRUM** (*Arvense*) spicis conicis laxè bracteis dentato-setaceis. Flor. Seuc. 511. *Cow Wheat with loose conical spikes, and bristly indented bractes.* Melampyrum purpurascens comâ. C. B. P. 234. *Cow Wheat with purplish tops.*
4. **MELAMPYRUM** (*Nemorosum*) floribus secundis lateralibus bracteis dentato cordato lanceolatis, summis, coloratis sterilibus, calycibus lanatis. Flor. Succ. 512. *Cow Wheat with fruitful lateral flowers, heart shaped bractes, sterile coloured tops, and woolly empalements.*

ments. Melampyrum comâ cæruleâ. C. B. P. 234. *Cow Wheat with blue tops.*

These plants are seldom cultivated in gardens. The first sort grows naturally in woods in many parts of England. The second sort grows plentifully in Bedfordshire and Cambridgeshire. The fourth sort grows in the northern parts of Europe. The third sort grows naturally in some of the sandy lands in Norfolk, tho' not in great plenty; but in West Friesland and Flanders, it grows very plentifully among the Corn; and Clusius says, it spoils their bread, making it dark; and that those who eat of it used to be troubled with heaviness of the head, in the same manner as if they had eaten Darnel or Cockle: but Mr. Ray says, He has eaten of this bread very often, but could never perceive that it gave any disagreeable taste, or that it was accounted unwholesome by the country people, who never endeavour to separate it from the Corn: and Tabernæmontanus declares, he has often eaten it without any harm; and says, it makes a very pleasant bread. It is a delicious food for cattle, particularly for fattening of oxen and cows, for which purpose it may be cultivated.

The seeds of these plants should be sown in the autumn soon after they are ripe, otherwise it seldom grows the first year; when the plants come up, they must be weeded in the spring while young, and as soon as they begin to shew their flowers, the cattle may be fed upon it; but they should be confined to a certain space, and not permitted to run over the whole field to trample it down, which would destroy a great part of it.

The third and fourth sorts make a pretty appearance, with their purple and blue tops, during the months of July and August. They are all of them annual plants.

MELANTHIUM, Star-flower.

The CHARACTERS are,

The flower has no empalement (unless the corolla is so called) it hath six oblong, oval, spreading petals, which are permanent, and six slender erect stamina inserted above the tails, with globular summits, with a streaked globular germen, supporting three curved distinct styles, crowned by obtuse stigma; the germen afterward turns to an oval capsule, having three cells, which are united within, containing several oval compressed seeds.

This genus of plants is ranged in the third section of Linnæus's sixth class, intitled Hexandria Trigynia, the flower having six stamina and three styles.

The SPECIES are,

1. MELANTHIUM (*Virginicum*) petalis unguiculatis. Lin. Sp. Plant. 483. *Star-flower with tender nail-shaped petals.* Asphodelo affinis Floridana, ramoso caule, floribus ornithogali obsoletis. Pluk. tab. 434. f. 8.
2. MELANTHIUM (*Sibericum*) petalis sessilibus. Amoen. Acad. 2. p. 349. *Star-flower with sessile petals.* Ornithogalum spicis florum longissimis ramosis. Flor. Siber. p. 45.
3. MELANTHIUM (*Punctatum*) petalis punctatis, foliis cucullatis. Amoen. Acad. 6. *Star-flower with punctated petals, and hooded leaves.*

The first sort grows naturally in Virginia and in other parts of North America, but being a plant of little beauty, is seldom cultivated except in botanic gardens; the flower-stalks of this rises from six to eight inches high, branching upward into three or four divisions, garnished below the flower with two or three linear leaves. The flowers are composed of six spreading petals of a dusky worn-out colour, which are rarely succeeded by seeds in England.

If the roots of this plant are planted in a border of light earth, not too dry, they will thrive and produce their flowers here, but seldom increase.

The second sort grows naturally in Siberia, so is at present a stranger in England, but may be propagated here (if once obtained) by planting the bulbous roots in an east border.

The third sort grows at the Cape of Good Hope, so is too tender to thrive in the open air in England. But if the roots are planted in a border, covered in win-

ter with a garden frame, and treated in the same way as is directed for the Ixia, they will thrive and flower annually.

MELASTOMA A. Lin. Gen. Plant. 481. Grossularia. Sloan. Hist. Jam. Plum. Sp. 18. The American Gooseberry-tree, vulgò.

The CHARACTERS are,

The flower has a permanent empalement of one leaf, swelling like a bladder, and obtuse. It hath five roundish petals, which are inserted into the border of the empalement, and ten short stamina, terminated by long erect summits a little curved. Under the flower is situated a roundish germen, supporting a slender style, crowned by an incurved indented stigma. The germen afterward turns to a berry with five cells, covered by the empalement which crowns it, and contains many small seeds.

This genus of plants is ranged in the first section of Linnæus's tenth class, intitled Decandria Monogynia, which includes those plants whose flowers have ten stamina and one style.

The SPECIES are,

1. MELASTOMA (*Plantaginis folio*) foliis denticulatis ovatis acutis. Lin. Sp. Plant. 389. *Melastoma with oval, acute-pointed, indented leaves.* Grossularia Americana, plantaginis folio amplissimo. Plum. Sp. 18.
2. MELASTOMA (*Acinodendron*) foliis denticulatis subtrinerviis ovatis acutis. Lin. Sp. Plant. 558. *Melastoma with oval indented leaves ending in acute points, having three veins.* Grossularia alia plantaginis folio, fructu rariore violaceo. Plum. Sp. 18.
3. MELASTOMA (*Hirta*) foliis denticulatis quinquenerviis, ovato-lanceolatis caule hispido. Lin. Sp. 390. *Melastoma with spear-shaped indented leaves, with five veins, and a prickly stalk.* Grossularia plantaginis folio angustiore hirsuto. Plum. Sp. 18.
4. MELASTOMA (*Holosericca*) foliis integerrimis trinerviis oblongo-ovatis tomentosis racemis brachiatis, spicis bipartitis. Lin. Sp. 559. *Melastoma with very entire oblong oval leaves, which are woolly on their under side, and spikes of flowers dividing in two parts.* Arbor racemosa Brasiliensis, folio Malabathri. Breyn. Cent. tab. 2 & 3.
5. MELASTOMA (*Grossularioides*) foliis lanceolatis utrinque glabris nervis tribus ante basin coeuntibus. Hort. Cliff. 162. *Melastoma with spear-shaped leaves smooth on both sides, and three veins which join before they reach the base.* Grossularia fructu non spinoso, Malabathri foliis oblongis, floribus herbaceis racemosis, fructu nigro. Sloan. Cat. 165.
6. MELASTOMA (*Bicolor*) foliis lanceolatis, nervis tribus longitudinalibus, subtus glabris coloratis. Hort. Cliff. 162. *Melastoma with spear-shaped leaves having three longitudinal veins, smooth and coloured on their under side.*
7. MELASTOMA (*Malabathrica*) foliis lanceolato-ovatis quinquenerviis scabris. Flor. Zeyl. 171. *Melastoma with spear-shaped oval leaves which are rough, and have five veins.* Melastoma quinque nervia hirta major, capitulis sericeis villosis. Burm. Zeyl. 155. tab. 73.
8. MELASTOMA (*Lævigata*) foliis oblongo-ovatis minutissime dentatis infernè sericeis quinquenerviis, floribus racemosis. *Melastoma with oblong oval leaves, having very small indentures on the edges, and silky on their under side, with five veins, and flowers growing in long bunches.* Grossulariæ fructu, arbor maximo non spinosa, Malabathri folio maximo inodora, flore racemoso albo. Sloan. Cat. Jam. 165.
9. MELASTOMA (*Petiolatis*) foliis denticulatis ovatis acuminatis, infernè nitidissimis, petiolis longissimis. *Melastoma with oval acute-pointed leaves, which are indented on their edges, very shining on their under side, and have very long foot-stalks.*
10. MELASTOMA (*Umbellata*) foliis cordatis acuminatis integerrimis, infernè incanis, floribus umbellatis. *Melastoma with heart-shaped, acute-pointed, entire leaves, hoary on their under side, and flowers growing in umbels.* Sambucus Barbadenfis dicta, foliis subincanis. Pluk. Phyt. tab. 221. fol. 6.
11. MELASTOMA (*Racemosa*) foliis oblongo-cordatis acuminatis, denticulato-ferratis, floribus racemosis sparsis.

M E L

sis. *Melastoma* with oblong, heart-shaped, acute-pointed leaves, having sawed indentures, and flowers growing thinly in long bunches.

12. MELASTOMA (*Verticillata*) foliis ovato-lanceolatis, quinquenerviis, subtus aureis, floribus verticillatis, caule tomentoso. *Melastoma* with oval spear-shaped leaves having five veins, which are of a gold colour on their under side, and flowers growing in whorls, with a woolly stalk.

13. MELASTOMA (*Acuta*) foliis lanceolatis acutis denticulatis infernè incanis trinerviis, floribus racemosis. *Melastoma* with acute spear-shaped leaves which are indented on their edges, hoary on their under side, have three veins, and flowers growing in bunches.

14. MELASTOMA (*Glabra*) foliis ovato-lanceolatis acuminatis integerrimis, utrinque glabris trinerviis, floribus racemosis. *Melastoma* with entire, oval, spear-shaped leaves ending in acute points, having three veins, and smooth on both sides, with flowers growing in long bunches. Arbor Syriamensis, canellæ folio utrinque glabro. Pluk. Phyt. tab. 249. fol. 5.

15. MELASTOMA (*Quinquenervia*) foliis ovatis quinquenerviis scabris, floribus racemosis alaribus. *Melastoma* with oval rough leaves having five veins, and flowers growing in bunches from the sides of the branches.

16. MELASTOMA (*Oxandria*) foliis lanceolatis trinerviis glabris, marginibus hispidis. *Melastoma* with smooth spear-shaped leaves having three veins, and hairy prickles on the border.

17. MELASTOMA (*Aspera*) foliis ovatis quinquenerviis glabris, marginibus hispidis. *Melastoma* with oval smooth leaves, having five veins, and hairy prickly borders.

18. MELASTOMA (*Scabrosa*) foliis ovato-lanceolatis scabris acuminatis quinquenerviis, floribus racemosis. *Melastoma* with oval, spear-shaped, acute-pointed leaves, having five veins, and flowers growing in long bunches.

The title of this genus of plants was given to it by Professor Burman, of Amsterdam, in the Thesaurus Zeylanicus; some of these plants have been titled Sambucus, others Christophoriana, and to some of the species Dr. Plukenet gave the title of Acidendron; but Sir Hans Sloane and Father Plumier, gave them the title of Grossularia, from whence I have applied the English name of Gooseberry to them, which is the name by which some of the sorts are known in America.

The first sort rises about four or five feet high, the stem and branches being covered with long russet hairs; the leaves are placed on the branches opposite; they are five inches long and two broad, and are also covered with the same russet down, having five ribs or veins running through the leaves from end to end, but the three inner join before they reach the base, with small transverse ribs; the fruit is produced at the end of the shoots, which is a pulpy blue berry, as large as a Nutmeg.

The second sort grows to be a large tree, having many crooked branches, covered with a brown bark, the leaves placed opposite on the branches; these are smooth, entire, and above five inches long, and two broad in the middle, with three deep veins running through them; both sides of these leaves are of a light green and smooth, and are sharply indented on their edges, ending in acute points. The fruit grows in loose spikes at the end of the branches; they are thinly placed on the spikes, and are of a Violet colour.

The third sort grows to the height of twenty feet, with a large trunk, covered with a russet bark: the leaves of this tree are very large, being above seven inches long, and three and a quarter broad, of a dark russet colour on their upper side, but of a yellowish russet on their under, soft to the touch, having a soft down over them; the stalks are covered with rough hairs, and the leaves are placed by pairs on the branches, which make a beautiful appearance when the trees are viewed at a distance.

The fourth sort seldom grows more than eight or ten feet high, the leaves are about four inches long,

M E L

having three veins, which join before they reach the base; they are entire, and are of a fawn colour on their under side, but of a light green on their upper; these are placed by pairs on the branches.

The fifth sort seldom grows more than seven or eight feet high, spreading out into many branches, which are covered with a smooth purple bark; they are slender, and are garnished with spear-shaped leaves, five inches long and two broad in the middle, where they are broadest; they are smooth on both sides, their edges are entire, and they terminate in acute points. The flowers are produced in pretty long hanging bunches, of an herbaceous colour, with long styles which are stretched out a good length beyond the petals; and are permanent; the fruit is small, and black when ripe.

The sixth sort rises four or five feet high, dividing into many slender branches, which are smooth, and garnished with spear-shaped leaves three inches long, and one and a quarter broad, of a lucid green on the upper side, but white on the under, having three longitudinal veins which join before they reach the base; these are entire, and placed alternately on the branches. The flowers are produced in a loose panicle at the end of the branches; they are small, white, and have pretty long tubes; these are succeeded by small purple fruit.

The seventh sort rises with an angular stalk six or seven feet high, sending out branches opposite, which are garnished with spear-shaped, oval, rough leaves, placed by pairs; they are hairy, of a dark green on their upper side, but of a pale green on their under. The flowers are produced at the end of the branches, two or three standing together; they are large, and of a Rose colour, inclining to purple, sitting in large hairy empalements; these are succeeded by roundish purple fruit crowned by the empalement, which are filled with a purple pulp surrounding the seeds.

The eighth sort grows to the height of twenty feet, with a large strait stem, covered with a gray bark, and at the top divides into many angular branches; these are garnished with oblong oval leaves near a foot long, and six inches broad in the middle, of a dark green on their upper side, but silky on their under, with five strong longitudinal veins; they are indented on their edges, and placed opposite. The flowers are produced in loose long bunches at the end of the branches; these are white, and are succeeded by roundish purple fruit, filled with pulp, in which the seeds are lodged.

The ninth sort rises with a strong erect stalk near thirty feet high, covered with a gray bark, dividing at the top into several angular compressed branches, which are garnished with oval leaves indented on their edges; they are seven inches long and almost five broad, standing by pairs opposite on very long foot-stalks, of a lucid green on their upper side, but of a pale gold colour and fatty on their under, with five strong longitudinal veins, and a great number of smaller transverse ones. The flowers are produced in loose panicles at the end of the branches; they are white, and are succeeded by purple fruit, about the same size as those of the former.

The tenth sort rises with a shrubby stalk ten or twelve feet high, covered with a hairy bark, and divides into many branches toward the top, which are garnished with heart-shaped leaves ending in acute points; they are five inches long and three broad toward their base, entire in their borders, of a dark green on their upper side, but hoary on their under, with five longitudinal veins, and many smaller transverse ones; these are placed opposite, and stand upon hairy foot-stalks, two inches and a half in length. The flowers are produced at the end of the branches, in a sort of umbel; they are of a pale Rose colour and pretty large, sitting on hairy empalements; these are succeeded by small black fruit, a little larger than Elder-berries.

The eleventh sort rises with a shrubby stalk about eight or nine feet high, covered with a dark brown bark,

bark, and divides at the top into many straggling branches, which are garnished with oblong heart-shaped leaves six inches long, and three broad toward their base, ending in acute points, indented on their edges with sharp serratures; they are smooth on both sides, and of a light green colour. The flowers are produced in very loose bunches at the end of the branches; they are small, of an herbaceous colour, and are succeeded by small fruit, of a dark colour when ripe.

The twelfth sort rises with a shrubby stalk five or six feet high, dividing into many smaller branches, which are covered with a hairy woolly bark, of a rusty iron colour; these are garnished with oval spear-shaped leaves, one inch and a half long, and three quarters of an inch broad in the middle; they are of a dark green on their upper side, and of a rusty iron colour on their under, having five longitudinal veins; they are placed opposite, and sit close to the branches. The flowers come out in whorls at the joints of the stalks; they are small, of a purplish colour, and are succeeded by small black fruit.

The thirteenth sort is a low shrub, seldom rising more than three feet high, dividing at the bottom into slender branches, which are garnished with spear-shaped leaves, ending in acute points; these are five inches long, and one and a half broad in the middle, sawed on their edges, of a dark green on their upper side, but of a hoary white on their under, having three longitudinal veins; they are placed opposite, upon short foot-stalks. The flowers are produced in loose bunches at the end of the branches; they are white, and succeeded by small purple fruit.

The fourteenth sort hath a shrubby stalk eight or nine feet high, divided toward the top into many slender branches which are smooth, garnished with oval spear-shaped leaves, which are seven inches long and three broad, ending in acute points; they are entire on their edges, and smooth on both sides, standing opposite, and have three longitudinal veins. The flowers are produced in loose panicles at the end of the branches, and are succeeded by very small purple fruit.

The fifteenth sort rises with several shrubby stalks five or six feet high, dividing into several crooked branches, garnished with oval leaves three inches long, and almost as much broad, having five longitudinal veins; they are rough, of a dark green on their upper side, but of a pale green on their under, indented on their edges, standing upon very hairy foot-stalks; they are sometimes opposite, and at others alternate, on the branches. The flowers are produced in very loose bunches, which come out from the side of the stalks; they are small, of an herbaceous colour, and are succeeded by small purplish fruit, filled with very small seeds.

The sixteenth sort rises with a shrubby stalk seven or eight feet high, and divides into many smooth branches, which are garnished with spear-shaped leaves about four inches long, and one inch and a quarter broad in the middle; they are smooth on both sides, of a dark green colour, and have three longitudinal veins; the edges of these leaves are closely set with bristly stinging hairs. The flowers are produced in loose bunches at the end of the branches; they are small, of a purplish colour, and are succeeded by very small black fruit.

The seventeenth sort is in many parts like the former, but the leaves are oval, a little more than two inches long, and one and a quarter broad; these have five longitudinal veins, and are smooth on both sides, of a dark green colour, and stand opposite on short foot-stalks. The flowers grow in loose bunches at the end of the branches, they are larger than those of the former sort, but are of the same colour. The edges of the leaves of this sort are closely set with stinging hairs, as those of the other.

The eighteenth sort rises with a shrubby stalk eight or nine feet high, dividing into branches standing opposite, as do also the leaves, which are seven inches

long and three broad; rough on their surface, entire on their edges, ending in acute points; they are of a light green on both sides, and stand upon short foot-stalks. The flowers are produced in pretty large loose panicles at the end of the branches; they are small, white, and are succeeded by small, round, purple fruit.

All the sorts are natives of the warm parts of America, where there are many more species than are here enumerated. Most of these here mentioned, were found by the late Dr. Houstoun, growing naturally in Jamaica, from whence he sent many of their seeds to Europe, some of which succeeded; but most, if not all the plants which were raised from them, were lost in the severe winter in 1740, since which time they have not been recovered in Europe.

There is great beauty in the diversity of the leaves of these plants, many of them being very large, and most of them are of different colours on the two surfaces, their under side being either white, gold colour, or russet, and their upper of different shades of green, so that they make a fine appearance in the hothouse all the year; indeed, their flowers have no great beauty to recommend them, but yet for the singular beauty of their leaves, these plants deserve a place in all curious collections, as much as most other sorts.

There are very few of these plants at present in any of the European gardens, which may have been occasioned by the difficulty of bringing over growing plants from the West-Indies; and the seeds being small when they are taken out of the pulp, soon become dry, so seldom succeed. The best way to obtain these plants is, to have the entire fruits put up in dry sand as soon as they are ripe, and forwarded by the soonest conveyance to England; these should be immediately taken out when they arrive, and the seeds sown in pots of light earth, and plunged into a moderate hot-bed of tanners bark. When the plants come up, and are fit to remove, they must be each planted into a small pot of light earth, and plunged into the tan-bed; and may afterward be treated in the manner directed for the ANNONA, to which I shall desire the reader to turn, to avoid repetition.

MELIA. Lin. Gen. Plant. 473. Azederach. Tourn. Inst. R. H. 616. tab. 387. The Bead-tree.

The CHARACTERS are,

The empalement of the flower is small, erect, and of one leaf, cut into five points at the top, which are obtuse. The flower hath five long, narrow, spear-shaped petals which spread open, and a cylindrical nectarium of one leaf, the length of the petals, indented at the brim in ten parts. It has ten small stamina inserted in the top of the nectarium, terminated by summits which do not appear above it, with a conical germen supporting a cylindrical style, crowned by an obtuse indented stigma. The germen afterward turns to a soft globular fruit, including a roundish nut having five rough furrows, and five cells, each containing one oblong seed.

This genus of plants is ranged in the first section of Linnæus's tenth class, intitled Decandria Monogynia, which includes those plants whose flowers have ten stamina and one style.

The SPECIES are,

1. MELIA (*Azedarach*) foliis bipinnatis. Flor. Zeyl. 162. *Melia with double winged leaves.* Azederach. Dod. Pempt. 848. *The Bead-tree, or False Sycamore.*
2. MELIA (*Azedirachta*) foliis pinnatis. Hort. Cliff. 161. *Melia with winged leaves.* Olea Malabarica, fraxini folio. Pluk. Alm. 269.

The first sort grows naturally in Syria, from whence it was brought to Spain and Portugal, where it is now become as common almost, as if it were a native of those countries. This in warm countries grows to a large tree, spreading out into many branches, which are garnished with winged leaves, composed of three smaller wings, whose lobes are notched and indented on their edges; they are of a deep green on their upper side, and paler on their under. The flowers come out from the side of the branches in long loose bunches;

M E L

bunches; they are composed of five long, narrow, spear-shaped petals, of a blue colour, and are succeeded by oblong fruit as large as a small Cherry, green at first, but when ripe changes to a pale yellow, inclosing a nut with five deep furrows, having four or five cells, in each of which is lodged one oblong seed. This produces its flowers in England in July, but are not often succeeded by seeds here; it drops its leaves in the autumn, and puts out fresh in the spring. The pulp which surrounds the nut, is said to have a deadly quality if eaten; and if mixed with grease, and given to dogs, it will kill them. The nuts are bored through, and strung by the Roman Catholics to serve as beads.

There has been of late years some of these plants introduced to the islands in the West-Indies, where I am informed they continue flowering, and produce their fruit most part of the year. The fruit I have received from thence by the title of Indian Lilac, from which I have raised many of the plants, and find them to be the same as that from Syria.

This sort is propagated by seeds (which may be obtained from Italy or Spain, where these trees annually produce ripe fruits in the gardens where they are planted;) the seeds or berries should be sown in pots filled with good fresh light earth, and plunged into a moderate hot-bed of tanners bark, where (if the seeds are fresh) they will come up in about a month or five weeks time. When the plants are come up they should be frequently watered, and should have a large share of free air, by raising the glasses every day; in June they should be exposed to the open air, in a well sheltered situation, that they may be hardened before winter. In October the pots should be removed under a hot-bed frame, where they may enjoy free open air when the weather is mild, and be covered in hard frost. During the winter season they must be refreshed gently with water, but by no means repeat this too often, nor give them too much at a time; for their leaves being off, they will not be in a condition to throw off a superfluity of moisture.

In March following, you may shake out the plants from the seed-pots and divide them, planting each into a separate small pot, filled with light fresh earth, plunging them into a moderate hot-bed, which will greatly promote their rooting, and increase their growth, but they must not be drawn too much; and in June you should remove them out into the open air as before, and during the three or four winters, while the plants are young, you must shelter them, to secure them from the cold; but when the plants are grown pretty large and woody, they will endure to be planted in the open air against a south wall. The best season for this is in April, at which time you should shake them out of the pots, being careful not to break the earth from the roots, but only pare off with a knife the outside of the ball of earth; then open your holes and put in the plants, closing the earth to their roots, observing if the weather is dry, to give them some water, which should be repeated twice a week until the plants have taken root; but you must observe to plant them on a dry soil, otherwise they will be liable to miscary in severe frosty weather.

The second sort grows naturally in India, where it becomes a large tree; the stem is thick, the wood of a pale yellow, and the bark of a dark purple colour and very bitter. The branches extend wide on every side, which are garnished with winged leaves, composed of five or six pair of oblong acute-pointed lobes, terminated by an odd one; these are sawed on their edges, of a light green colour, and a strong disagreeable odour; they stand upon pretty long foot-stalks, which come out sometimes opposite, and at others they are alternate. The flowers are produced in long branching panicles which proceed from the side of the branches; they are small, white, and sit in small empalements, which are cut in five acute segments; these are succeeded by oval fruit of the size of small Olives, which are green, afterward yellow, and when ripe, they change to a purple colour;

M E L

the pulp which surrounds the nut is oily, acrid, and bitter; the nut is white, and shaped like that of the former. It grows in sandy land, both in India and the island of Ceylon, where it is always green, and produces flowers and fruit twice a year.

This sort is now very rare in England, and also in the Dutch gardens, where some years past it was more common; it is propagated by seeds in the same way as the other sort, but being much tenderer, the plants should be kept constantly in the tan-bed while young. In the summer they may be placed under a frame, but in winter they must be removed into the bark-stove, and treated in the same way with other plants from the same countries. When the plants have obtained strength, they may be treated more hardily, by placing them in winter in a dry stove, and in the middle of summer they may be placed abroad for two or three months in a warm sheltered situation, but they should not remain too long abroad; and during the winter season they should be sparingly watered: with this management the plants will produce flowers annually, and as they retain their leaves all the year, they are ornamental in winter in the stove. The first sort is commonly called, *Zizyphus alba*, in Portugal and Spain, and in Italy, *Pseudocycanorus*. It was by most of the modern botanists titled, *Azederach*, but Dr. Linnæus has altered it to this of *Melia*, which was by Theophrastus applied to a species of Ash.

MELIANTHUS. Tourn. Inst. R. H. 430. tab. 245. Lin. Gen. Plant. 712. [*μελιανθος*, of *μελι*, honey, and *ανθος*, a flower.] Honey Flower.

The CHARACTERS are,

The flower has a large, coloured, unequal empalement, divided into five segments; the two upper are oblong and erect, the lower is short, and shaped like a bag. The middle are spear-shaped and opposite. It hath four narrow spear-shaped petals, reflexed at their points, spreading open outward, and shaped like the empalement into two lips, connected on their sides. It has a nectarium of one leaf, situated in the lower segment of the empalement, and fastened with it to the receptacle; it is short, compressed on the sides, and cut on the margin. It hath four erect awl-shaped stamina, the two under being somewhat shorter than the other, terminated by oblong heart-shaped summits. In the center is situated a four-cornered germen, supporting an erect style, crowned by a quadrifid stigma. The germen afterward becomes a quadrangular capsule with distended cells, divided by partitions in the center, each containing one almost globular seed, fixed to the center of the capsule.

This genus of plants is ranged in the second section of Linnæus's fourteenth class, which includes those plants whose flowers have two long and two shorter stamina, and their seeds are included in empalements.

The SPECIES are,

1. MELIANTHUS (*Major*) stipulis solitariis petiolo adnatis. Hort. Cliff. 492. *Honey Flower with single stipule growing close to the foot-stalk.* Melianthus Africanus. H. L. B. 414. *Greater African Honey Flower.*
2. MELIANTHUS (*Minor*) stipulis geminis distinctis. Hort. Cliff. 492. *Smaller Honey Flower with two distinct stipule.* Melianthus Africanus minor scetidus. Com. Rar. Pl. 4. tab. 4.

The first sort grows naturally at the Cape of Good Hope, from whence it was brought to Holland in the year 1672; this hath a ligneous perennial root, which spreads far on every side, from which arise many ligneous stalks which rise four or five feet high, and are herbaceous toward the top, where they are garnished with large winged leaves, which embrace the stalks with their base, where they have a large single stipule fastened on the upper side of the foot-stalk, with two ears at the base, which also embrace the stalk. The leaves have four or five pair of very large lobes, terminated by an odd one; these are deeply jagged on their edges into acute segments, and between the lobes runs a double leafy border or wing on the upper side of the midrib, so as to connect the base of the lobes together; these are also deeply jagged in

M E L

the same manner as the lobes; they are of a gray colour. The flowers are produced in pretty long spikes, which arise from between the leaves toward the top of the stalks; they are of a brown or chocolate colour, and are formed like the lip flowers, but have four narrow petals, in which it differs from the other plants of this class with lip flowers; these are succeeded by oblong four-cornered capsules, divided by a central partition into four cells, each containing one roundish seed; this plant flowers in June, but unless the season proves warm, they are not succeeded by seeds in England.

This plant was formerly preserved in green-houses as a tender exotic, but if planted in a dry soil and a warm situation, it will endure the cold of our ordinary winters very well; and if in a severe frost the tops of them should be destroyed, yet the roots will abide, and put forth again the succeeding spring, so that there is no great danger of losing it; and the plants which grow in the open air always flower much better than those which are preserved in the green-house, as they are less drawn, which always is hurtful to the flowering of plants; for it rarely happens that any of the plants of this sort, which are placed in the green-house do flower, for they are apt to draw up tall and weak, which prevents their flowering, and those branches which produce flowers, generally decay soon after; so that although the stems become woody, yet they are not of long duration, but the roots spread where they have room, and send out a great number of stalks annually; and when the plants grow in the full ground, most of those stalks which are not injured by frost, seldom fail to flower the spring following, so that the surest method to have them flower, is to cover the shoots of these plants in frosty weather with Reeds or mats, to prevent their tops being killed by the cold; therefore it is the best way to plant them close to a good aspected wall, and on a dry rubbish, in which they will not shoot so vigorous as in good ground, so will be less succulent, and therefore not so liable to suffer by cold; but if the winter proves severe, the stalks may be fastened up to the wall, and covered to protect them; for want of this care the stalks are frequently killed to the ground in winter, so that there is seldom any flowers produced.

This plant may be propagated by taking off its suckers or side shoots, any time from March to September, observing to chuse such as are furnished with fibres, and after they are planted and taken root, they will require no farther care but to keep them clear from weeds: they may be also propagated by planting cuttings, during any of the summer months, which, if watered and shaded, will take root very well, and may afterwards be transplanted where they are designed to remain.

The second sort is also a native of the country about the Cape of Good Hope, from whence it was brought to Europe; this rises with round, soft, ligneous stalks five or six feet high, which send out two or three branches from their side, garnished with winged leaves like those of the former sort, but not half so large; these have two distinct stipulæ adhering to their foot-stalks; they are of a deep green on their upper side, and whitish on their under. The flowers come out from the side of the stalks in loose hanging panicles, each sustaining six or eight flowers, which are shaped like those of the first sort, but smaller; the lower part of the petals are green, their upper part are of a Saffron colour, and on the outside, in the swelling part of the petals, is a blush of fine red; these have two long and two shorter stamina, which are terminated by yellow summits. The flowers are succeeded by four-cornered seed-vessels, which are shorter than those of the first sort, in which are lodged four oval seeds in separate apartments; this flowers at the same season with the former.

This sort does not spread its roots as the first, so is not propagated with so great facility, but cuttings of this sort planted upon an old hot-bed, whose heat is

M E L

over, and covered close with bell or hand-glasses to exclude the air, will take root pretty freely; these may be planted in pots, and sheltered in the winter under a common frame for a year or two till they have obtained strength, then they may be planted in a warm border, and treated in the same way as the former sort, with which management I have seen them flower much better than any of those which have been treated more tenderly, and these plants have perfected their seeds in good seasons.

MELICocca. See SAPINDUS.

MELILOTUS. See TRIGONELLA.

MELISSA. Tourn. Inst. R. H. 193. tab. 91. Lin. Gen. Plant. 647. [so called of μέλι, honey, because the bees procure it from this plant; it is also called Melissophyllon, μέλι, and φύλλον, a leaf, q. d. Honey Leaf.] Baum.

The CHARACTERS are,

The empalement of the flower is of the open, bell-shape, angular kind, streaked with one leaf, whose brim is formed into two lips; the upper lip is indented in three parts, which are spread open and reflexed; the under lip is short, acute, and indented in two parts. The flower is of the lip kind, having a cylindrical tube; the chaps are gaping, the upper lip is short, erect, forked, and roundish, indented at the end. The under lip is trisid, the middle part being the largest. It hath four awl-shaped stamina, two of which are as long as the petal, but the other are but half so long; they are terminated by small summits, which join by pairs. It hath a quadrifid germen, supporting a slender style the length of the petal, which, with the stamina, are situated under the upper lip, and is crowned by a slender, bifid, reflexed stigma. The germen afterward turns to four naked seeds, sitting in the empalement.

This genus of plants is ranged in the first section of Linnaeus's fourteenth class, which includes the plants whose flowers have two long and two short stamina, whose seeds are naked.

The SPECIES are,

1. MELISSA (*Officinalis*) racemis axillaribus verticillatis, pedicellis simplicibus. Lin. Sp. Plant. 592. Baum with whorled bunches of flowers proceeding from the sides of the stalks, having single foot-stalks. Melissa hortensis. C. B. P. 229. Garden Baum, or common Baum.
2. MELISSA (*Romana*) floribus verticillatis sessilibus, foliis hirsutis. Baum with whorls of flowers sitting close to the stalks, and hairy leaves. Melissa Romana, mollior hirsuta & graveolens. H. R. Par. Roman Baum with soft hairy leaves, and a strong smell.
3. MELISSA (*Grandiflora*) pedunculis axillaribus dichotomis longitudine florum. Lin. Sp. Plant. 592. Baum with foot-stalks arising from the wings of the stalk, which are divided in forks, and are the length of the flowers. Calamintha magno flore. C. B. P. 229. Calaminth with a large-flower.
4. MELISSA (*Calamintha*) pedunculis axillaribus dichotomis longitudine foliorum. Lin. Sp. Plant. 593. Baum with foot-stalks arising from the wings of the stalk, which are forked, and as long as the leaves. Calamintha vulgaris & officinarum Germaniæ. C. B. P. 228. Common officinal Calamint of the Germans.
5. MELISSA (*Nepeta*) pedunculis axillaribus dichotomis folio longioribus, caule decumbente. Lin. Sp. Plant. 593. Baum with foot-stalks arising from the wings of the stalk, which are forked, and longer than the leaves, with a declining stalk. Calamintha pulegii odore five nepeta. C. B. P. 228. Calamint with the scent of Penny Royal, or Cat Mint.
6. MELISSA (*Cretica*) racemis terminalibus, pedunculis solitariis brevissimis. Lin. Sp. Plant. 593. Baum with spikes of flowers terminating the stalks, growing upon very short single foot-stalks. Calamintha incana ocy-mi foliis. C. B. P. 228. Heavy Calamint with Bays leaves.
7. MELISSA (*Majeranifolia*) foliis ovatis glabris, floribus verticillatis sessilibus, pedunculis solitariis brevissimis. Baum with oval smooth leaves, and flowers growing in whorls, sitting close to the branches, which have very short single stalks. Calamintha Romana, majorana folio,

M E L

folio, pulegii odore. Boec. Mus. *Roman Calamint with a Marjoram leaf, and the scent of Penny Royal.*

8. MELISSA (*Iruticosa*) fruticosa, ramis attenuatis virgatis, foliis subtomentosis. Lin. Sp. Plant. 593. *Shrubby Baum with slender twig-like branches, and leaves which are woolly on their under side.* Calamintha Hispanica frutescens, mari folio. Tourn. Inst. 194. *Shrubby Spanish Calamint with a Marum leaf.*

The first sort grows naturally on the mountains near Geneva, and in some parts of Italy, but is cultivated here in gardens as a medicinal and culinary herb. It has a perennial root, and an annual stalk, which is square, branching, and rises from two to three feet high, garnished with leaves set by pairs at each joint, which are two inches and a half long, and almost two inches broad at their base, growing narrower toward the top, indented about their edges, and the lower ones standing upon pretty long foot-stalks. The flowers grow in loose small bunches at the wings of the stalk, in whorls, standing upon single foot-stalks; they are of the lip kind, the upper lip standing erect and is forked; the under lip is divided into three parts; the middle one is roundish, and indented at the top. The flowers are white, and appear in July. The whole plant has a pleasant scent, somewhat like Lemons.

It is reckoned to be cordial, cephalic, and good for all disorders of the head and nerves; there is a simple water of this herb. It is also used as Tea, and is by some greatly esteemed for that purpose; there is a variety of this with striped leaves.

This plant is easily propagated by parting of the root; the best time for this is in October, that the offsets may have time to get root before the frosts come on. The roots may be divided into small pieces with three or four buds to each, and planted two feet apart in beds of common garden earth, in which they will soon spread and meet together; the only culture it requires is to keep it clean from weeds, and cut off the decayed stalks in autumn, stirring the ground between the plants.

The second sort grows naturally about Rome, and in several parts of Italy; this hath a perennial root, and an annual stalk like the former. The stalks are slender, the leaves are much shorter than those of the former sort, and the whole plant is hairy, and of a strong disagreeable odour. The flowers grow in whorls, sitting pretty close to the branches, and are smaller than those of the first sort; it flowers about the same time. It is seldom preserved in gardens, but may be cultivated in the same way as the former.

The third sort grows naturally in the mountains of Tuscany and Austria, but is preserved in many English gardens for the sake of variety. It hath a perennial root, and an annual stalk, which rises about a foot high, garnished at each joint with two leaves standing opposite, which are an inch and a half long, and three quarters of an inch broad, sawed on their edges, of a lucid green on their upper side, and whitish on their under: from the wings of the stalks come out single foot-stalks half an inch long, which divide into two smaller, and each of these sustain two flowers upon short separate foot-stalks. The flowers are large, of a purple colour, and shaped like those of the other species. It flowers in June, and the seeds ripen in August. This may be propagated in the same way as the first sort, and the plants may be treated in the same manner.

The fourth sort is the common Calamint of the shops, which grows naturally in many parts of England, so is seldom kept in gardens. It hath a perennial root, from which arise several square stalks near a foot long, which are hairy, and garnished with two roundish leaves at each joint, about the size of those of Pot Marjoram, a little indented on their edges, and of a strong penetrating odour. The flowers come out in whorls on the side of the stalks, upon foot-stalks, which divide by pairs, and are as long as the leaves; these sustain several small bluish flowers, which appear

M E L

in July, and are succeeded each by four small, roundish, black seeds. The herb is used in medicine, and is hotter, and abounds with more subtle and volatile parts than Mint. It provokes urine, brings down the menses, opens the liver, and is good for coughs. This may be planted in gardens, and treated in the same way as the common Baum.

The fifth sort is found in greater plenty than the fourth, growing wild in England. The stalks of this are longer and bend towards the ground. The leaves are larger, and more indented on their edges, and have a very strong scent like Penny Royal. The whorls of flowers are set closer together than those of the fourth sort, but in other respects they agree.

The sixth sort grows naturally in the south of France and in Italy; this is not of so long duration as the former sorts, seldom continuing more than two or three years. The stalks are slender, a little ligneous, and are garnished with small, roundish, hoary leaves, placed opposite at each joint. The flowers are produced in whorls toward the upper part of the stalks, which are terminated by a loose spike; they are small and white, shaped like those of the other species, and appear in June; these are succeeded by seeds, which ripen in autumn, and if they are permitted to scatter, there will be a sufficient supply of young plants.

The seventh sort grows naturally in Italy; this is a biennial plant, whose stalks are about eight inches long, declining toward the ground, and are garnished with roundish leaves about the size of Marjoram, of a light green colour. The flowers come out in close whorls on the upper part of the stalks, each standing upon a short separate foot-stalk; they are large, and of a bright purple colour, appearing in July and August, and the seeds ripen in autumn; this is propagated by seeds, which should be sown soon after they are ripe, and then the plants will come up in the spring; but when the seeds are not sown till the spring, they seldom grow till the next year. The plants may also be propagated by cuttings, which if planted in the summer, and shaded from the sun, will take root very freely. If these plants are on a warm border, they will live through the winter, but to preserve the species, a plant or two should be kept in pots, and sheltered under a frame in winter.

The eighth sort grows naturally in Spain; this hath slender shrubby stalks about nine inches long, which put out small side branches opposite, and are garnished with small, hoary, oval-pointed leaves, placed by pairs; these have much the appearance of those of the Marum. The flowers grow in whorled spikes, at the end of the stalks; they are small and white, appearing in July, and the seeds ripen in autumn. The whole plant has a strong scent of Penny Royal; this plant is of as short a duration as the seventh sort, and may be propagated either by seeds or cuttings in the same way as the seventh, and the plants require the same treatment.

MELISSA TURCICA. See DRACOCEPHALON.

MELITTIS. Greater Dead Nettle.

The CHARACTERS are,

It hath an erect, taper, bell-shaped empalement, having two lips; the upper is tall and indented, the under is short and bifid; the flower is ringent, the tube is longer than the empalement, the chaps are thicker; the upper lip is roundish, plain, and erect; the lower is trifid, spreading, and obtuse. It hath four stamina, which are awl-shaped, situated under the upper lip, two being a little longer than the other, terminated by bifid obtuse summits, which are placed a cross; it hath an obtuse, quadrisid, hairy germen supporting a slender style, crowned by a bifid acute stigma. The flower is succeeded by four seeds which ripen in the empalement.

This genus of plants is ranged in the first section of Linnæus's fourteenth class, intitled Didynamia Gymnospermia, the flowers having two long and two short stamina, and are succeeded by four naked seeds sitting in the empalement.

We

M E L

We know but one SPECIES of this genus, viz.
MELITTIS (*Melyssophyllum*.) Hort. Cliff. 309. *Greater Dead Nettle*. *Melissa*. Fuchsi.

This plant grows naturally in some woods in the West of England and in Wales, Germany and near Montpellier. It hath a perennial root, which in the spring sends up three, four, or more stalks, according to the age and strength, which rise a foot and a half high; these are square, and garnished with leaves like those of the common Dead Nettle, but are much larger, rougher, and stand on longer foot-stalks, two being placed opposite at each joint. The flowers come out at the joints of the stalks, just above the foot-stalks of the leaves; they are in shape like those of the Dead Nettle, but are much larger, of a redder purple colour, and the upper lip grows erect. These appear in May, when the plants make a handsome appearance, and if the season does not prove hot, the flowers will continue in beauty upward of three weeks. As the plants do rarely produce good seeds in the gardens, so they are usually propagated by parting the roots; but where the plants are intended for ornament, the roots should not be disturbed oftener than every third year; nor should they then be divided into small parts, lest thereby they should not flower the first year. The best time to remove and part the roots is the beginning of October, that they may have time to get root before the frost comes on. They should have a loamy soil and an east exposure, where the plants will thrive and produce flowers in plenty.

M E L O. Tourn. Inst. R. H. 104. tab. 32. *Cucumis*. Lin. Gen. Plant. 969. [it takes its name of *Μήλον*, an Apple, because the fruit resembles an Apple.] The Melon.

The CHARACTERS are,

It hath male and female flowers on the same plant. The male flowers have a bell-shaped empalement of one leaf, whose border is terminated by five awl-shaped bristles. The flower is of one petal, which is bell-shaped, fastened to the empalement, and cut into five segments at the brim; these are veined and rough. It hath three short stamina inserted in the empalement, and are joined together, two of which have bifid points. The summits are linear, and run up and down on the outside of the stamina, to which they adhere. The female flowers have no stamina or summits, but have a large oval germen situated below the flower, supporting a short cylindrical style, crowned by three thick gibbous stigmas. The germen afterward turns to an oval fruit with several cells, filled with oval, acute-pointed, compressed seeds, inclosed in a soft pulp.

This genus of plants is by Dr. Linnæus joined with the *Colocynthus* and *Anguria*, to the *Cucumis*, making them only species of the same genus, which, according to his system, may be allowable; but whoever will admit the fruit as a characteristic note to distinguish the genera, will find marks to separate them; and however properly these may be put together in a system of botany, yet in a work of this nature it cannot be admitted.

There is a great variety of this fruit cultivated in the different parts of the world, and in this country there are too many of them propagated, which are of no value, especially by those who supply the markets, where their size is chiefly regarded; so that by endeavouring to augment their bulk, the fruit is rendered of no value; I shall therefore only mention a very few of the varieties, which are the most deserving of care, excluding the common Melons, as being unworthy of the trouble and expence in cultivating.

The sort of Melon which is in the greatest esteem among all the curious in every part of Europe, is the *Cantaleupe*; which is so called from a place about fourteen miles from Rome, where the pope has a country seat, in which place this fruit has been long cultivated; but it was brought thither from that part of Armenia which borders on Persia, where this fruit is in so great plenty, that a horse-load is sold for a French crown. The flesh of this Melon, when in perfection, is delicious, and does not offend the most tender stomachs, so may be eaten with safety. The

M E L

Dutch are so fond of this fruit, as to cultivate very few other sorts, and by way of pre-eminence, call it only by the appellation of *Cantaleupe*, and never join the title of Melon to it, which they apply indifferently to all the other sorts. The outer coat of this is very rough, and full of knobs and protuberances like warts; it is of a middling size, rather round than long, and the flesh is for the most part of an Orange colour, though there are some with a greenish flesh, but I have never met with any of that colour so good as those of the other.

The *Romana* is by some much esteemed, and when the fruit is well conditioned, the plants in perfect health, and the season dry, it is a good Melon, and may be brought forwarder in the season than the *Cantaleupe*; therefore those who are desirous of early Melons may cultivate this sort.

The *Succado* is also a good sort, and may also be cultivated for early fruit, but these must give way to the *Cantaleupe*, when that is in season.

The *Zatte* is also a very good Melon, but very small. The fruit of this is seldom bigger than a large Orange; it is a little flatted at the two ends, and the outer coat is warted like the *Cantaleupe*, but there is so little flesh in one of these fruit, that they are scarce worthy the trouble of propagating.

The small Portugal Melon, which is by some called the *Dormer Melon*, is a pretty good fruit, and the plants generally produce them in plenty, so by many people this is preferred to most other, especially those who love a plenty, and are not so nice in distinguishing the quality: this may also be cultivated for an early crop.

But the best Melon for this purpose is the *Black Galloway*, which was brought from Portugal by Lord Galloway many years since, but of late years is rarely to be met with in England, it having been degenerated by growing among other sorts. The fruit of this sort will ripen in a shorter time from its first setting, than any other which I have yet seen, and when suffered to ripen naturally, is not a bad fruit.

The few varieties here mentioned, are sufficient to satisfy the curious, who may be fond of variety, for there are scarce any other which deserve the trouble; and indeed those who have a true taste for this fruit, seldom cultivate any but the *Cantaleupe*; but as I before observed, where this fruit is desired early in the season, the *Cantaleupe* is not so proper as some of the other, therefore a few plants of one of the other sorts should be raised earlier in the spring, but should be in a different part of the garden from the *Cantaleupe* Melons; for when two sorts of Melons grow near, they cannot be preserved perfectly right; therefore the Dutch and German gardeners are very careful in this respect, and in order to keep the sort in perfection, do not plant any other sort of Melon, Cucumber or Gourd, near these, lest, by the impregnation of the farina of those other, these fruit should be rendered bad; and in this particular, I am convinced, from long experience, they are right; and from the not observing this, many persons who are lovers of this fruit, have gradually diminished their goodness, without knowing the cause, and have imputed it to the long cultivating from the seeds sowed in the same garden, believing it absolutely necessary to procure seeds from a distant place frequently to preserve them good: indeed, where a person can securely depend on the care and skill of those he procures the seeds from, it is a very good method to exchange seeds now and then; but there are so few who are exact in making choice of the fruits from which they save the seeds, or careful enough to do it themselves, but often depend on others to clean the seed, that I should advise every one to do it himself, which is the sure way to have it good; for I have frequently been deceived myself, by depending on the fidelity and skill of others; nor could I procure any of these seeds from *Cantaleupe* which were good, until my much honoured friend, the Chevalier Rathgeb, sent me plentifully of it from thence; though I had often been supplied

M E L

supplied with seeds by persons who I thought could not be deceived in their choice, and who lived near the place of their growth.

Before I quit this head, I beg leave to caution all persons against depending upon seeds which are brought from abroad, either by those persons who import them for sale, or gentlemen who frequently bring or send over these seeds to their friends, for it seldom happens that any of these prove tolerable. I have been so often deceived by these myself, as to determine never to make trial of any of these seeds again, unless I receive them from a person who is skilful, and who eat of the fruit himself of which he sowed the seeds; for in Italy, Spain, Portugal, and many parts of France, the gardeners are very careless in the choice of all their seeds, but of the Melons they are remarkably so; and as for those which come from Constantinople, Aleppo, and other parts of Turkey, I have rarely seen one Melon produced from those seeds which was tolerable.

The seeds of Melons should not be sown until they are three years old, nor would I chuse to sow them when they are more than six; for although they will grow at ten or twelve years old, yet the fruit which are produced from those old seeds are seldom so thick fleshed, as those which come from seeds which are fresher: and it is the same of light seeds, which swim upon water, when they are taken out of the pulp, for I have made some trials of these, and have had them grow at three years old; but not one of the Melons produced on these plants was near so deep fleshed, as those which grew upon plants raised from heavy seeds taken out of the same fruit, though they grew in the same bed, and were cultivated exactly in the same manner; nor was their flesh so firm, but rather inclining to be meally; therefore I would not advise the sowing of these light seeds, nor those which are very old.

Having thus largely treated of the choice of the sorts, and of the seeds, I shall next proceed to the method of cultivating them, in order to obtain plenty of good fruit: the method which I am going to prescribe being very different from what has been constantly practised in England, will, I doubt not, be objected to by many; but it is what has been practised in all the good gardens in Holland and Germany, where the Cantaleupe Melon is produced in great plenty and perfection; and from several years experience, I have found this to be the only method in which these Melons can be cultivated with success; and I am likewise convinced of its being the best way to obtain plenty of any other sort of Melon.

It is common to hear many persons valuing themselves upon having two or three early Melons, which, when brought to the table are not better than a Pumpkin, and these are procured at a great expence and with much trouble; and in order to have them ripe a little earlier than they would naturally come, if suffered to grow to their full size, the stem upon which the fruit grows is commonly twisted, to prevent the nourishment entering the fruit, whereby the growth is checked; then the fruit is closely covered with the mowings of Grass-plats, laid of a sufficient depth to cause a fermentation, by which the fruit becomes coloured: but where this unnatural method is practised, the fruit has little flesh; and that has neither moisture, firmness, or flavour; so that after four months attendance, with a great expence of dung, &c. there may, perhaps, be three or four brace of Melons produced, which are fitter for the dunghill than the table. Therefore my advice is, never to attempt to have these fruit ripe earlier than the middle or latter end of June, which is generally soon enough for this climate; and from that time to the end of September, they may be had in plenty, if they are skilfully managed; and when the autumn has continued favourable, I have had them very good in the middle of October.

But in order to continue this fruit so long, the seeds must be sown at two or three different seasons: the first

M E L

should be sown about the middle or end of February, if the season proves forward; but if it is otherwise, it will be better to defer it till the end of that month; the future success greatly depends on the raising the plants in strength, which cannot be so well effected, if the weather should prove so bad after the plants are come up, as that a sufficient quantity of fresh air cannot be admitted to them, therefore it is not advisable to be too early in sowing the seeds.

When the season is come, these seeds may be sown on the upper side of a Cucumber-bed, where there are any; and if there are none, a proper quantity of new horse dung must be provided, which must be thrown in a heap to ferment, and turned over, that it may acquire an equal heat, in the same manner as hath been directed for Cucumbers; and the plants must be raised and managed in the same manner as hath been directed for them, until they are planted where they are to remain for good, to which article the reader is desired to turn, to avoid repetition.

The second season for sowing of these seeds is about the middle of March, and both these sowings must be understood to be planted under frames; for those which are designed for bell or hand-glasses, or to be covered with oil papers, should not be sown till about a week in April; for when these are sown earlier, if the plants are properly managed, they will grow so long, as to extend their shoots to the sides of the glasses, before it will be safe to let them run out; for it often happens in this country, that we have sharp morning frosts in the middle of May; so that if the ends of these Vines are then without the glasses, if they are not covered with mats to guard them against the frost, they will be in danger of suffering greatly therefrom; and, on the other hand, if the plants have spread so much as to fill the glasses, and not permitted to run out, they will be in equal danger of suffering by their confinement from the heat of the sun in the day time; therefore it is that I should advise the putting of the seed rather a little later into the hot-bed for the glasses, than those which are to be covered with the oil papers. Nor will the times here mentioned be found too late, for I have put the seeds of Cantaleupe Melons into a hot-bed the third of May, which were not transplanted, but remained where they were sown, and covered with oiled paper; and from this bed I cut a large crop of good fruit, which ripened about the latter end of August, and continued till the end of October. This I only mention, to shew what has and may be done, though it must not be always depended on.

But we next come to the making and preparing of the beds, or, as the gardeners term it, the ridges, into which the plants are to be put out to remain; these should always be placed in a warm situation, where they may be defended from all cold and strong winds, for the east and north winds are generally very troublesome in the spring of the year; so that if the place be exposed to those aspects, it will be difficult to admit a proper share of fresh air to the young plants; and if it is much exposed to the south-west winds, which often are very boisterous in summer and autumn, these will turn up and displace the Vines, whereby they will suffer greatly; therefore the best position for these beds is where they are open to the south, or a little inclined to the east, and sheltered at a distance by trees from the other points: this place should be inclosed with a good Reed fence, which is better for this purpose than any other inclosure, because the winds are deadened by the Reeds, and are not reverberated back again, as they are by walls, pales, and other close fences; but in making the inclosure, it should be extended to such distance every way from the beds, as not to obstruct the sun's rays during any part of the day; this should have a door wide enough to admit of wheelbarrows passing, to carry in dung, earth, &c. and it should be kept locked, that no persons should be allowed to go in but those who have business; for ignorant persons, having often curiosity to look into the beds, open the glasses

M E L

and let the cold air to the plants, and frequently leave the glasses in part open; or sometimes when they are raised by the gardener to admit the fresh air, the tilts are thrown down, so that the air is excluded; all which are very injurious to the young plants, as is also the handling of the fruit after it is set; therefore none should be admitted, but when the person who is intrusted with the care of them is there.

The next thing is the preparation of the earth for these plants, in which the Dutch and German gardeners are very exact: the mixture which they generally prepare is of the following sorts; of hazel loam, one third part; of the scouring of ditches or ponds a third part, and of very rotten dung a third part; these are mixed up at least one, and often two years, before they make use of it, frequently turning it over, to incorporate their parts and sweeten it; but the compost in which I find these plants succeed best in England, is two thirds of fresh gentle loam, and one third of rotten neats dung; if these are mixed together one year before it is wanted, so as to have the benefit of a winter's frost and summer's heat, observing to turn it over often, and never suffer weeds to grow upon it, this will be found equal to any other compost whatever.

As these plants succeed best when they are planted young, so before the plants appear there should be a quantity of new dung thrown in a heap, proportionable to the number of lights intended, allowing about fifteen good wheelbarrows full to each light; this must be two or three times turned over, to prepare it (as hath been directed for Cucumbers) and in a fortnight it will be fit for use, at which time the trench must be dug to receive the dung, where the bed is intended; this must be made wider than the frames, and in length proportional to the number of frames intended. As to the depth, that must be according as the soil is dry or wet; but in a dry ground it should not be less than a foot, or a foot and a half deep; for the lower these beds are made the better they will succeed, where there is no danger of their suffering by wet. In the well laying and mixing of the dung, the same care must be taken as hath been advised already for Cucumbers, which in every respect must be the same for these beds. When the bed is made, the frames should be placed over it to keep out wet; but there should be no earth laid upon it till after it has been three or four days made, and is found of a proper temperature of heat; for many times these beds will heat so violently when they are first made, as to burn the earth, if covered with it; and when this happens, it is much the best way to take this earth off again, for the plants will never thrive in it. As soon as the bed is found to be of a proper warmth, the earth should be laid upon it, which at first need not be more than two inches thick, except in the middle of each light, where the plants are to be placed, where there must be a hill raised fifteen inches high or more, terminating in a flat cone; in two or three days after the earth is put on the bed, it will be of a proper temper to receive the plants; then in the evening you may transplant the plants, but always do it when there is little wind stirring: in taking up the plants, their roots should be carefully raised with a trowel, so as to preserve all their fibres; for if these are broken off, the plants do not soon recover this; or if they do, they are generally weaker, and seldom make so good Vines as those which are more carefully removed; for these plants are more nice and tender in transplanting than those of Cucumber, especially the Cantaleupe Melon; which, if it is not planted out, soon after the third, (or what the gardeners call the rough) leaf is put out, they are long recovering their vigour; so that when it happens that the beds cannot be ready for them in time, it will be a good method to plant each plant into a small pot while they are young, and these may be plunged into the hot-bed where they were raised, or into the Cucumber-bed where there is room, so that they may be brought for-

M E L

ward; and when the bed is ready, these may be turned out of the pots, with the whole ball of earth to their roots, whereby they will receive no check in removing; and this latter method is what I should prefer to any other for the Cantaleupe, because there should never be more than one plant left to grow in each light; therefore in this method there will be no necessity of planting more, as there will be no danger of their succeeding; whereas in the common way, most people plant two or more plants in each light, for fear some should miscarry. When the plants are placed on the top of the hills, they should be gently watered, which should be repeated once or twice after till the plants have taken good root, after which they seldom require more; for when they receive too much wet, they often canker at the root, and when that happens they never produce good fruit. When the plants have established themselves well in the new beds, there should be a greater quantity of earth laid on the bed, beginning round the hills where the plants grow, that their roots may have room to strike out; and as the earth is put in from time to time, it must be trodden or pressed down as close as possible; and it should be raised at least a foot and a half thick upon the dung all over the bed, observing also to raise the frames, that the glasses may not be too near the plants, lest the sun should scorch them.

When the plants have gotten four leaves, the top of the plants should be pinched off with the finger and thumb, but not bruised or cut with a knife, because in either of these cases the wound will not so soon heal over: this pinching is to cause the plants to put out lateral branches, for these are what will produce the fruit; therefore, when there are two or more of these lateral shoots produced, they must also be pinched, to force out more; and this must be practised often, that there may be a supply of what the gardeners call runners, to cover the bed. The management of these beds must be nearly the same as hath been directed for the Cucumbers, therefore I need not repeat it here; but shall only observe, that the Melons require a greater share of air than Cucumbers, and very little water; and when it is given to them, it should be at a distance from their stems.

If the plants have succeeded well, they will spread over the bed, and reach to the frames, in about five or six weeks, at which time the alleys between the beds should be dug out; or where there is but one bed, there should be a trench made on each side, of about four feet wide, as low as the bottom of the bed, and hot dung wheeled in, to raise a lining to the same height as the dung of the bed, which should be trodden down close, and afterward covered with the same earth as was laid upon the bed, to the thickness of a foot and a half or more, treading it down as close as possible; this will add to the width of the bed, so much as to make it in the whole twelve feet broad, which is absolutely necessary, for the roots of the plants will extend themselves quite through it; and it is for want of this precaution, that it is common to see the Vines of Melons decay, before the fruit is well grown; for where there is no addition made to the width of the bed, the roots will have reached the sides of the beds by the time that the fruit appears, and having no more room to extend themselves, their extremities are dried by the sun and air, which is soon discovered by the plants hanging their leaves in the heat of the day, which is soon attended with a decay of many of those leaves which are near the stem, and the plants from that time gradually languish, so that the fruit cannot be supplied with nourishment; but when ripe, will be found to have little flesh, and that mealy and ill flavoured; whereas those plants which have sufficient breadth for their roots to run, and the earth laid of a proper depth and closely trod down, will remain in vigour until the frost destroys them, so that I have had a second crop of fruit on them, which have sometimes ripened well; but all the first were excellent, and of a larger size than

M E L

than these sorts usually grow: the leaves of these plants were very large, and of a strong green, so that they were in the utmost vigour; whereas, in most places where the Cantaleupe Melons have been raised in England, the beds have been no wider than they were first made, and perhaps not more than three inches thickness of earth upon them, so that the plants have decayed many times without producing a single fruit; and from thence people have imagined, that this sort of Melon was too tender for this climate, when their ill success was entirely owing to their not understanding their culture.

There is also another advantage attending this method of widening the beds, as above directed, which is that of adding a fresh warmth to the beds, by the hot dung, which is buried on each side, which will cause the dung in the bed to renew its heat; and as the plants will by this time shew their fruit, this additional heat will be of great service in setting the fruit, especially if the season should prove cold, as it often happens in this country in the month of May. When the beds are made up in the manner here directed, and the Vines have extended so far as to fill the frames, and want more room, the frames should be raised up with bricks about three inches high, to admit the shoots of the Vines to run from under them; for if the plants are strong, they will run six or seven feet each way from the stems; for which reason, I caution every one to allow them room, and to put but one plant in each light; for when the Vines are crowded, the fruit seldom will set well, but will drop off when they are as large as an egg; therefore the frames which are designed for Melons should not be made small, but rather six feet wide; for the wider these are, the better will the plants thrive, and produce a greater plenty of fruit.

There is no part of gardening, in which the practitioners of this art differ more than in the pruning and managing of these plants: nor are there any rules laid down in the several books in which the culture of Melons have been treated of, by which any person can be instructed; for there is such inconsistency in all their directions, and what is worse, the greatest part of them are absurd, so that whoever follows them can never hope to succeed; therefore I shall, in as few words as possible, give such plain directions, as I hope will be sufficient to instruct any person, who is the least conversant in these things.

I have before advised the pinching off the ends of the plants as soon as they have a joint, in order to get lateral shoots, which are by the gardeners called runners; and when these shoots have two or three joints, to pinch off their tops to force out more runners, because it is from these that the fruit is to be produced; but after a sufficient number are put out, they should not be stopped again, but wait for the appearance of the fruit, which will soon come out in plenty; at which time the Vines should be carefully looked over three times a week, to observe the fruit, and make choice of one upon each runner, which is situated nearest the stem, having the largest foot-stalk, and that appears to be the strongest fruit, and then pinch off all the other fruit which may appear on the same runner; also pinch off the end of the runner at the third joint above the fruit, and if the runner is gently pinched at the next joint above the fruit, it will stop the sap and set the fruit. There is also another method practised by some gardeners to set this fruit, which is the taking off some of the male flowers, whose farina are just ripe and fit for the purpose, laying them over the female flowers, which are situated on the crown of the young fruit, and with their nails gently strike the male flowers to shake the farina into the female flowers, whereby they are impregnated, and the fruit soon after will swell, and shew visible signs of their being perfectly set; so that where the plants are under frames, and the wind excluded from them, which is necessary to convey the farina from the male to the female flowers, this practice may be very necessary. The taking off all the other fruit

M E L

will prevent the nourishment being drawn away from the fruit intended to grow, which, if they were all left on the plant, could not be supplied with sufficient nourishment; so that when they come to be as large as the end of a man's thumb, they frequently drop off, and scarce one of them sets, which will be prevented by the method before directed: but there are some persons, who are so covetous of having a number of fruit, as not to suffer any to be taken off, whereby they generally fail in their expectation. My allowing but one fruit to be left upon each runner is, because if half these stand there will be full as many fruit as the plant can nourish; for if there are more than eight upon one plant, the fruit will be small and not so well nourished: indeed, I have sometimes seen fifteen or twenty Melons upon one plant, but these have generally been of the smaller kinds, which do not require so much nourishment as the Cantaleupes, whose skins are of a thick substance; so that where a greater number are left of them than the plants can well supply, their flesh will be remarkably thin.

As I before advised the stopping or pinching off the runners three joints above the fruit, so by this there will be fresh runners produced a little below the places where the others were pinched; therefore it is, that I advise the careful looking over the Vines so often, to stop these new runners soon after they come out, as also to pull off the young fruit which will appear; and this must be repeated as often as is found necessary, which will be until those intended to stand are grown so large as to draw all the nourishment which the plants can supply, for then the plants will begin to abate of their vigour. These few directions, if properly made use of, is all the pruning which is necessary to be given them; but at the same time when this is practised, it may be necessary to give some water to the plants, but at a distance from their stems, which will be of service to set the fruit and cause it to swell, but this must be done with great caution.

The glasses of the hot-bed should also be raised high, to admit a large share of air to the plants, otherwise the fruit will not set; and if the season should prove very warm, the glasses may be frequently drawn off, especially in an evening, to receive the dews, provided there is but little wind stirring; but the glasses should not remain off the whole night, lest the cold should prove too great; but in warm weather, the glasses may be kept off from ten in the morning till evening.

When the plants have extended themselves from under the frames, if the weather should alter to cold, it will be necessary to cover their extremities every night with mats; for if these shoots are injured, it will retard the growth of the fruit, and often proves very injurious to the plants: and now what water is given to the plants, should be in the alleys between the beds; for as the roots of the Vines will by this time have extended themselves through the alleys, so when the ground there is well moistened, the plants will receive the benefit of it; and by this method, the stems of the plants will be preserved dry, whereby they will continue sound; but these waterings should not be repeated oftener than once a week in very dry warm weather, and be sure to give as much air as possible to the plants when the season is warm.

Having given full instructions for the management of those Melons which are raised under frames, I shall next proceed to treat of those which are raised under bell or hand-glasses. The plants for these must be raised in the same manner as hath been already directed, and about the latter end of April, if the season proves forward, will be a good time to make the beds; therefore a sufficient quantity of hot dung should be provided, in proportion to the intended number of glasses, allowing six or eight good wheelbarrows of dung to each glass. Where there is but one bed, which is proposed to be extended in length, the trench should be dug out four feet and a half wide, and the length according to the number of glasses;

M E L

glasses, which should not be placed nearer than four feet to each other; for when the plants are too near each other, the Vines will intermix, and fill the bed so closely as to prevent the fruit from setting: in digging the trench, it should be so situated, as to allow for the widening of the bed three or four feet on each side; the depth must be according as the soil is dry or wet; but, as was before observed, if the soil is so dry as that there is no danger of the beds being hurt by the wet, the lower they are made in the ground the better: in the making of the beds, the same regard must be had to the well mixing and laying of the dung as was before directed; and after the dung is laid, there should be a hill of earth raised, where each plant is to stand, one foot and a half high; the other part of the bed need not as yet be covered more than four inches thick, which will be sufficient to keep the warmth of the dung from evaporating; then the glasses should be placed over the hills, and set down close, in order to warm the earth of the hills to receive the plants; and if the beds work kindly, they will be in a proper temperature to receive the plants in two or three days after making; then the plants should be removed, in the same manner as was before directed; and if they are in pots, so that there will be no danger of their growing, there should but one plant be put under each glass; and if they are not in pots, there should be two, one of which may be afterward taken away, if they both grow. These plants must be watered at first planting, to settle the earth to their roots, and shaded every day until they have taken new root; and if the nights prove cold, it will be proper to cover the glasses with mats, to preserve the warmth of the bed.

Where there are several of the beds intended, they should be placed at eight feet distance from each other, that there may be a proper space left between them, to be afterward filled up, for the root of the Vines to have room for extending themselves, for the reasons before given.

When the plants have taken good root in the beds, their tops must be pinched off; and their pruning, &c. must, from time to time, be the same as for those under the frames. In the day time, when the weather is warm, the glasses should be raised on the opposite side to the wind, to admit fresh air to the plants; for where this is not observed, they will draw up weak and sickly, therefore all possible care should be taken to prevent this; for if the runners have not proper strength, they can never supply the fruit with nourishment.

When the plants are grown so long as to reach the sides of the glasses, if the weather proves favourable, the glasses must be set on three bricks, so as to raise them about two inches from the surface of the beds, to give room for the Vines to run out from under them; but when this is done, the beds should be covered all over with earth to the depth of one foot and a half, and trod down as close as possible; and if the nights should prove cold, there should be a covering of mats put over the beds, to prevent the cold from injuring the tender shoots of the Vines; but as the Vines of the Contaleupe Melons are impatient of wet, it will be necessary to arch the beds over with hoops to support the mats, that they may be ready for covering at all times when they require it; which is the only sure method to have these Melons succeed in England, where the weather is so very uncertain and variable; for I have had some beds of these Melons in as fine order under these glasses as could be desired, which were totally destroyed by one day's heavy rain in June.

After the thickness of earth is laid upon the beds, if the weather should prove cold, it will be advisable to dig trenches on each side of the beds, into which you should lay a sufficient quantity of hot dung, to make it of the same thickness with the bed, after the manner before directed for the frames; or if there is a sufficient quantity of hot dung ready, the whole space between the beds may be dug out and filled up with

M E L

the dung, laying thereon the earth a foot and a half deep, treading it down close; this new dung will add a fresh warmth to the beds, and cause the plants to shew fruit soon after.

The watering of these plants must be done with great caution, and not given to their stems; the pinching off the runners must also be duly attended to, as also the pulling off all superfluous fruit, to encourage those which are designed to remain: and in short, every thing before directed for those under frames, must likewise be observed for these; and the further care is, to cover them in all hard rains and cold nights, with mats, which, if performed with care, there will be little danger of their miscarrying, and these Vines will remain vigorous until the cold in autumn destroys them.

There have been many persons, who of late years have raised their Melons under oiled paper, and in many places they have succeeded well; but where this is practised, there must be great care taken not to keep these coverings too close over them; for where that is done, the Vines will draw very weak, and rarely set their fruit in any plenty; therefore where these coverings are proposed to be used, I should advise the bringing up of the plants under hand or bell-glasses, in the manner before directed, until they are grown far enough to be let out from under the glasses; and then, instead of the covering with mats, to put over the oiled paper; and if this covering is prudently managed, it will be the best that can be used. The best sort of paper for this purpose is that which is strong, and not of too dark a colour; and it should be done over with linseed oil, which will dry soon. There should be a proportionable number of sheets of this paper paited together, as will spread to the dimensions of the frame to which it is fastened; and if this is fixed to the frame, before the oil is rubbed over it, so much the better; but this should be done so long before they are used, as that the oil may be thoroughly dry, and the stench gone off, otherwise it will destroy the plants.

There are some persons who make these frames of broad hoops, in imitation of the covers of waggons; but as these are cumbersome to move, and there are no conveniencies for admitting air to the plants, but by raising the whole frame on one side, I prefer those made of pantile laths, framed like the ridge of a house; and each slope having hinges, may be raised at pleasure to admit the air to the plants; but as descriptions of these things are not well comprehended by persons not so conversant with them, I shall exhibit a figure of one of these frames, to be added to the article of Stoves.

The further management of the Melons, after their fruit is set, is to keep pulling off all the superfluous fruit, and to pinch off all weak runners, which may draw away part of the nourishment from the fruit; as also to turn the fruit gently twice a week, that each side may have equal benefit of the sun and air; for when they are suffered to lie with the same side constantly to the ground, that side will become of a pale or whitish colour, as if it were blanched, for want of the advantages of the sun and air. The plants will require a little water in very dry weather, but this should be given them in the alleys at a distance from the stems of the plants, and not oftener than once in a week or ten days, at which time the ground should be well soaked in the alleys. This will encourage the growth of the fruit, and cause the flesh to be thick; but the great caution which is necessary to be observed, is not to over-water the plants, which is certain injury to them: also be sure to give as much free air as possible, at all times, when the weather will permit, for this is absolutely necessary to render the fruit good.

When the fruit is fully grown, they must be duly watched to cut them at a proper time; for if they are left a few hours too long upon the Vines, they will lose much of their delicacy, therefore they should be
looked

looked over at least twice every day; and if those fruit which are intended for the table, are cut early in the morning, before the sun has warmed them, they will be much better flavoured; but if any should require to be cut afterward, they should be put into cold spring water, or ice, to cool them, before they are brought to the table: and those cut in the morning, should be kept in the coolest place till they are served up to table. The sign of this fruit's maturity is, that of its beginning to crack near the foot-stalk, and its beginning to smell, which never fail; for as these Cantaleupe Melons seldom change their colour until they are too ripe, that should never be waited for. The directions here given for the management of the Cantaleupe Melons, will be found equally good for all the other sorts, as I have fully experienced; for in the common method of managing them, where the earth is laid but three or four inches thick, the plants are very apt to decay before the fruit is ripe; for their roots soon reach the dung, and are extended to the sides of the bed, where their tender fibres are exposed to the air and sun, which cause the leaves of the plants to hang down in the heat of the day, so it is necessary to shade them with mats, to prevent their decay; and this also occasions the watering of the plants often to keep them alive, which is also prejudicial to their roots; whereas when the beds are made of a proper width, and earthed of a sufficient thickness, the plants will bear the strongest heat of the sun in this climate, without shewing the least want of moisture, or their leaves drooping, and they will continue in health till the autumn cold destroys them.

In saving of the seeds I need not repeat here, that only such should be regarded, which are taken from the firmest fruit, and those which have the highest flavour; and if these are taken out with the pulp entire, without displacing the seeds, and suffered to remain in the pulp two or three days before it is washed out, the better; and then to preserve only the heavy seeds, which sink in the water.

MELOCACTUS. } See CACTUS.
MELOCARDUUS. }
MELOCHIA, Jews Mallow.

The CHARACTERS are,

It hath a permanent empalement of one leaf, cut half way into five segments; the flower hath five large spreading petals; the stamina are involved in the tube of the germen, and have five summits. It has a roundish germen with five awl-shaped erect styles, which are permanent, crowned by single stigmas. The flower is succeeded by five-cornered roundish capsules, having five cells with two horns, in each cell is lodged one angular compressed seed.

This genus of plants is ranged in the first section of Linnæus's sixteenth class, intitled Monadelphia Pentandria; the flowers of this class have their stamina and styles connected in one house, and those of this section have but five stamina.

The SPECIES are,

1. MELOCHIA (*Pyramidata*) floribus umbellatis oppositis foliis, capsulis pyramidalis pentagonis, angulis acutis, foliis nudis. Hort. Cliff. 343. *Jews Mallow with umbellated flowers placed opposite to the leaves, and five-cornered pyramidal capsules.* Althæa Brasiliæna frutescens, incarnato flore, fagopyri semine. Pluk. Phyt. tab. 131. f. 3.
2. MELOCHIA (*Tomentosa*) floribus umbellatis axillariis, capsulis pyramidalis pentagonis, angulis mucronatis, foliis tomentosis. Lin. Sp. 943. *Jews Mallow with umbellated flowers at the wings of the stalk, five-cornered pyramidal capsules, and woolly leaves.* Abutilon herbaceum procumbens, betonicæ folio, flore purpureo. Sloan. Hist. Sp. 220.
3. MELOCHIA (*Depressa*) floribus solitariis capsulis depressis pentagonis, angulis obtusis ciliatis. Flor. Leyd. Prod. 348. *Jews Mallow with flowers growing singly, and five-cornered depressed capsules.* Abutilon Americanum, ribesii foliis, flore carneo, fructu pentagono aspero. Houst. MSS.

4. MELOCHIA (*Concatenata*) racemis confertis terminalibus, capsulis globosis sessilibus. Flor. Zeyl. 247. *Jews Mallow with clustered spikes terminating the stalks, and globular capsules sitting close.*
5. MELOCHIA (*Supina*) floribus capitatis, foliis ovatis serratis, caulibus procumbentibus. Lin. Sp. 944. *Jews Mallow with flowers in heads, oval-sawed leaves, and trailing stalks.* Alcea supina pusilla, geranii exigui maritimi folio & facie, maderaspatensis, fructu in summo caule glomerato, pericarpio duro. Pluk. Phyt. tab. 132. f. 4.

The first sort grows naturally in the Brazils as a common weed, having a stalk somewhat shrubby, which rises four or five feet high; the flowers are produced in umbels from the side of the stalk, opposite to the leaves; they are of a pale flesh colour, and are succeeded by pyramidal capsules with five corners having five cells, each containing one angular seed.

The second sort grows naturally in Jamaica, and other warm parts of America. This has a trailing herbaceous stalk, garnished with woolly leaves shaped like Betony. The flowers are produced in umbels at the wings of the stalk; they are of a purple colour, and are succeeded by pyramidal capsules, having five corners.

The third sort was discovered growing naturally at the Havannah, by the late Dr. Houstoun. This rises with a shrubby stalk five or six feet high, garnished with angular leaves resembling those of the Currant bush; the flowers are produced singly from the side of the stalk: they are of a flesh colour, and in shape like those of the small flowering Mallow; these are succeeded by rough five-cornered capsules, inclosing five Mallow-shaped seeds.

The fourth sort grows naturally in both Indies; this hath an herbaceous stalk, which is terminated by several oblong bunches of flowers, which are succeeded by globular capsules with five cells, in each of which is lodged a single seed.

The fifth sort grows naturally in India; this is an annual plant with trailing stalks which spread on the ground, garnished with small Betony-shaped leaves; the flowers and fruit are produced in clusters at the end of the branches.

These plants are preserved in botanic gardens for variety, but having little beauty they are rarely cultivated in other places; they are propagated by seeds which must be sown on a hot-bed, and when the plants come up, they should be treated in the same way as is directed for SIDA, to which the reader is desired to turn to avoid repetition. The first and third sorts are shrubby, so may with care be preserved thro' the winter in a stove, whereby good seeds may be obtained; for these seldom ripen their seeds well the first year, unless the plants are brought forward early in the spring, and the summer proves warm. The other three sorts generally ripen their seeds the same year they are sown.

MELON. See MELO.

MELONGENA. Tourn. Inst. R. H. 151. tab. 65. Solanum. Lin. Gen. Plant. 224. Mad Apple, by some called Egg Plant; in French, *Mayenne*.

The CHARACTERS are,

The flower has a permanent empalement of one leaf, which is deeply cut into five acute segments, which spread open. The flower hath but one petal, which is cut into five parts, which spread open and are reflexed. It hath five awl-shaped stamina, terminated by oblong summits which converge together. In the center is situated an oblong germen supporting a slender style, crowned by an obtuse stigma; the germen afterward becomes an oval or oblong fruit with one cell, which hath a fleshy pulp, filled with compressed roundish seeds.

This genus of plants is ranged in the seventh section of Tournefort's second class, which includes the herbs with a wheel-shaped flower of one leaf, whose pointal changes to a soft fruit. Dr. Linnæus has joined this genus, and the Lycopersicon of Tournefort, to the Solanum, making them only species of

that genus; but as the fruit of this genus has but one cell, so it should be separated from the Solanum, whose fruit have two cells, and of which there are so many species already known, that there need not be any addition of plants which can be separated with propriety added to it; he places it in the first section of his fifth class.

The SPECIES are,

1. MELONGENA (*Ovata*) caule inermi herbaceo, foliis oblongo-ovatis tomentosis integris, fructu ovato. *Mad Apple with a smooth herbaceous stalk, oblong, oval, woolly leaves, which are entire, and an oval fruit.* Melongena fructu oblongo violaceo. Tourn. Inst. 151. *Mad Apple with an oblong Violet-coloured fruit.*
2. MELONGENA (*Tereta*) caule inermi herbaceo, foliis oblongo-ovatis tomentosis, fructu tereti. *Mad Apple with herbaceous, smooth, oblong, oval, woolly leaves, and a taper fruit.* Melongena fructu tereti violaceo. Tourn. Inst. 151. *Mad Apple with a taper Violet-coloured fruit.*
3. MELONGENA (*Incurva*) caule inermi herbaceo, foliis oblongis sinuatis tomentosis, fructu incurvo. *Mad Apple with a smooth herbaceous stalk, oblong sinuated leaves which are woolly, and an incurved fruit.* Melongena fructu incurvo. Tourn. Inst. R. H. 152. *Mad Apple with an incurved fruit.*
4. MELONGENA (*Spinosa*) spinosa, foliis sinuatis-lacinatis, fructu tereti, caule herbaceo. *Mad Apple, with a prickly stalk and leaves which are cut into sinuses, a taper fruit, and an herbaceous stalk.* Solanum pomiferum fructu spinoso. J. B. 3. 619. *Apple-bearing Nightshade with a prickly fruit.*

The first sort grows naturally in Asia, Africa, and America, where the fruit is commonly eaten by the inhabitants; and it is cultivated in the gardens in Spain as an esculent fruit, by the title of Barenkeena; the Turks who also eat the fruit, call it Badinjan, the Italians Melanzana, and the inhabitants of the British islands in America, Brown John, or Brown Jolly. It is an annual plant with an herbaceous stalk, which becomes a little ligneous, and rises near three feet high, sending out many side branches, garnished with oblong oval leaves seven or eight inches long, and four broad; they are woolly, and their borders are very slightly sinuated, but not indented, standing without order upon very thick foot-stalks. The flowers come out singly from the side of the branches, having a thick fleshy empalement of one leaf, which is deeply cut into five acute segments, which spread open, and is armed with strong prickles on the outside. The flowers have one petal, which is cut at the brim into five segments, which expand in form of a star, and are a little reflexed; they are blue, and the summits which are connected together in the bosom of the flower are yellow. The flowers are succeeded by oval fleshy fruit, about the size and shape of a swan's egg, of a dark purple on one side, and white on the other. The flowers come out in June and July, and the fruit ripens in September.

There are the following varieties of these species; one with white fruit, called by some the Egg Plant; one with yellow fruit, and another with pale red fruit; all these varieties are generally constant, the seeds producing the same fruit as those from which they were taken, but as they only differ in colour, so I chuse not to enumerate them as distinct species.

The second sort differs from the first in the shape of the fruit, which is commonly eight or nine inches long, taper and strait; in other respects they are the same, but as this never varies when propagated in gardens, so there can be no doubt of their being distinct species. There are two varieties of this sort, one with a purplish fruit, and the other white, but the latter is the most common in England.

The third sort differs from the two former in the shape of the leaves, which are deeply sinuated on their borders. The fruit is oblong and incurved, of a yellowish colour, and larger at the end than in any other part.

The seeds of the fourth sort were sent me from India;

this differs greatly from either of the former. The stalks and leaves are armed with very strong thorns, and the leaves are larger, and deeply jagged on their sides. The flowers are larger, and of a deeper blue colour. The fruit is long, taper, and white.

These fruit are eaten by most of the inhabitants of the warm parts of the globe, and are esteemed a delicacy, but are supposed to have a property of provoking lust.

They are propagated by seeds, which must be sown upon a moderate hot-bed in March, and when the plants come up, they must be transplanted into another hot-bed about four inches asunder, observing to water and shade them until they have taken root; after which you must give them a great share of air when the weather is warm, otherwise they will draw up very weak. They must be also frequently watered, without which they will make but very indifferent progress; but when they are grown so strong as to fill the frame (which will be by the middle or end of May,) you must transplant them out into a rich spot of ground, at two feet distance, or in the borders of the pleasure-garden at the same distance from other plants, observing to preserve as much earth to the roots as possible when you take them up, otherwise they are subject to miscarry. You must observe to water them plentifully, and shade them until they have taken root, after which they will require but very little care, more than to keep them clear from weeds, and in very dry weather to give them some water.

About the middle of July the fruit will appear, at which time, if the weather should be very dry, you must often water them, which will cause the fruit to grow very large, and increase their number: toward the latter end of August their fruit will ripen, when you must preserve the seeds of each kind separate; but those for the table should be gathered before they are quite ripe.

These plants are only preserved as curiosities in the English gardens, the fruit being seldom eaten in this country, except by some Italians or Spaniards, who have been accustomed to eat them in their own countries.

MELOPEPO. See CUCURBITA.

MELONRY, or MELON GROUND, is an apartment in the kitchen-garden for the propagation of Melons only.

This spot of ground should be open to the south-east sun, but sheltered from the west, north-west, and north-east winds, by walls, pales, or hedges, the latter of these is the best; it should also be upon a dry soil, for nothing is more injurious to these plants than much wet; for in the spring of the year it often proves very wet weather, when, if the soil is very wet, there will be no making the ridges until it is very late. This should also be contrived as near to the dung as possible, which will save a great deal of labour in wheeling the dung; and, if there should be a pond of water near it, which, in very dry weather, will be very useful to water the Melons when it is necessary, though it is not often that water is wanted for this purpose in England.

As to the size of the ground, that must be proportioned to the quantity of ridges intended, which you may easily calculate, by allowing twelve feet breadth for every ridge, and the holes placed at about four feet asunder; but it is the best way to allow room enough where you are not streightened to it.

This ground should be inclosed with a Reed fence, and kept constantly locked up during the time that the Melons are growing, for if they are exposed to every person that walks in the garden (most of whom have a curiosity to handle the Vines, and look after the fruit,) it will be of ill consequence, nothing being more injurious to these plants than frequent tumbling or disturbing their leaves.

The common practice in most gentlemens gardens is, to inclose a spot of ground either with walls or pales, which they constantly appropriate to this purpose; but

M E L

but this is by no means a good method, for it rarely happens that these succeed well longer than two years in the same place, unless the soil be removed and fresh brought in, which is very expensive; therefore the best way is, to have a sufficient parcel of Reeds made into pannels, which may be annually moved from place to place, so that you need not continue your ridges longer than one year in the same place; and if you have a piece of ground which is large enough to divide into three or four such places, the fence may be every year removed till the whole has been occupied, after which you may return to the spot where you began, which, by that time, will be as good as fresh earth; and hereby, without much trouble, you may remove them every year, for as one of the sides will remain unremoved every time the fence is carried forward, the labour will not be so great as if it were wholly removed to some distance, and these Reed fences are much preferable to either walls or pales, for this purpose.

MELOTHRIA. Lin. Gen. Plant. 48.

The title of this genus was applied to it by Dr. Linnaeus in the Hortus Cliffortianus. By some authors it hath been placed under the genus of Cucumis, and by others under that of Bryonia; but the Doctor has removed this to a distance from either of those genera, on account of its having but three stamina; but Dr. Van Royen has brought it next to the genus of Bryonia again, as the plants have male and hermaphrodite flowers.

The CHARACTERS are,

The empalement of the flower is of one leaf, bell-shaped, and cut slightly at the brim into five parts, and in the hermaphrodite flowers, rests upon the embryo. The male flower is of one leaf, wheel-shaped, having a tube the length of the empalement. In the center of the hermaphrodite flower is situated the pointal, supporting a cylindrical style, attended by three conical stamina, which are inserted in the tube of the flower, and are extended to the same length; the male flowers have three stamina, terminated by blunt styles. The pointal afterward becomes an oval small berry, having three divisions, in which are lodged small flat seeds.

We have but one SPECIES of this plant, viz.

MELOTHRIA (Pendula.) Lin. Hort. Cliff. 490. *Small creeping Cucumber. Cucumis minima fructu ovali nigro laevi. Sloan. Hist. 1. p. 227. Smallest Cucumber with a smooth, black, oval fruit.*

This plant grows wild in the woods in Carolina, Virginia, and also in many of the islands in America; it creeps upon the ground with slender Vines, having angular leaves, somewhat resembling those of the Melon, but much smaller. These Vines strike out roots at every joint, which fasten themselves into the ground, and thereby a larger share of nourishment is drawn to the plants, by which means their stalks extend to a great distance each way, and closely cover the ground. The flowers are very small, in shape like those of the Melon, and of a pale sulphur colour. The fruit, in the West-Indies, grow to the size of a Pea, of an oval figure, and changes black when ripe; these are by the inhabitants sometimes pickled when they are green.

In England the fruit are much smaller, and are so hidden by the leaves, as to render it difficult to find them. The plants will not grow in the open air here, but the seeds must be sown upon a hot-bed, and if the plants are permitted, will soon spread over the surface of a large bed; and when the fruit is ripe, if they scatter their seeds, the plants will come up where the earth happens to be used on a hot-bed again, and if they are supplied with water, will require no farther care. This plant is in some gardens preserved for the sake of variety, but is of no use.

MENISPERMUM. Tourn. Act. R. Par. 1705. Lin. Gen. Plant. 1131. Moonseed.

The CHARACTERS are,

It hath male and female flowers on different plants; the male flowers have empalements composed of two short linear leaves, and have four oval spreading petals with-

M E N

out side, and eight oval concave petals within, which are smaller than those without, ranged in four series, and many cylindrical stamina which are longer than the petals, terminated by short obtuse summits having four lobes. The female flowers have the same empalement and corolla as the male, and have eight stamina with pellucid summits, which are fruitful. These have two oval incurved germina, supporting a solitary recurved style, crowned by a bifid stigma; the germen afterward become two roundish kidney-shaped berries of one cell, inclosing a large kidney-shaped seed.

This genus of plants is ranged in the tenth section of Linnaeus's twenty-second class, which includes those plants which have male and female flowers on different plants, and the male flowers have twelve stamina.

The SPECIES are,

1. **MENISPERMUM (Canadense)** foliis peltatis subrotundis angulatis. Hort. Cliff. 140. *Moonseed with target-shaped, roundish, angular leaves. Menispermum Canadense scandens, umbilicatis foliis. Tourn. Act. Par. 1705. Climbing Moonseed of Canada, with a navel-shaped leaf.*
2. **MENISPERMUM (Virginicum)** foliis cordatis peltatis lobatis. Flor. Virg. 40. *Moonseed with heart and target-shaped leaves, which have lobes. Menispermum folio hederaceo. Hort. Elth. 223. tab. 178. Moonseed with an Ivy leaf.*
3. **MENISPERMUM (Carinianum)** foliis cordatis subtus villosis. Lin. Sp. Plant. 340. *Moonseed with heart-shaped leaves, which are hairy on their under side.*

The first sort grows naturally in Canada, and most parts of North America, in the woods; this hath a thick ligneous root, from which are sent out many climbing stalks, which become ligneous, and rise to the height of twelve or fourteen feet, twisting themselves about the neighbouring plants for support; these are garnished with large, smooth, roundish leaves, whose foot-stalks are placed almost in the middle of the back of the leaves; on the upper side there is a hollow in that part of the leaf resembling a navel. The flowers come out in loose bunches from the side of the stalks; they are of an herbaceous colour, small, and composed of two tiers of oblong oval petals, very short stamina, with ten in the male flowers, terminated by single summits; the two germen situated in the center of the female flowers turn to so many channelled berries, each containing one kidney-shaped seed. It flowers in July, and the seeds ripen in autumn.

This sort may be easily propagated by laying down of the branches, which, if performed in autumn, will have made good roots by the following autumn, when they may be separated from the old plant, and transplanted where they are designed to remain; these plants require support, for their branches are slender and weak. In the country where it grows naturally, they climb up the trees to a considerable height, so that if these are planted near trees in wilderness quarters, where their stalks may have support, they will thrive better than in an open situation.

The second sort differs from the first in the shape of its leaves, which are angular, and sometimes heart-shaped; their foot-stalks join to the base of the leaves, so they have no umbilical mark on their surface. The stalks of this become ligneous, and rise nearly as high as those of the first sort, and the flowers and berries do not differ from them. It is also propagated after the same manner.

The third sort grows naturally in Carolina, from whence the seeds were sent to England; this has by some been supposed the same with the second sort, from which it differs in its branches, not becoming woody as those do. The stalks are herbaceous; the leaves are entire and hairy, and are not more than half so large as those of the second, nor is the plant so hardy, for in severe winters, those which are exposed to the open air are sometimes killed, whereas the second sort is never injured by cold. This sort does not produce any flowers in England, unless the season proves very warm.

This

This may be propagated by parting of the roots, which spread out on the side, so that part of them may be cut off every other year; the best time for doing this is in the spring, a little before the plants begin to shoot; these should be planted in a warm situation and have a light soil, for in strong land, where the wet is detained in winter, the roots are apt to rot; therefore if they are planted close to a wall exposed to the south or west, their stalks may be fastened against the wall, to prevent their trailing upon the ground; and in this situation the plants will frequently flower, and by having a little shelter in severe frost, their stalks may be preserved from injury.

There is little beauty in these plants, but yet they are preserved in many gardens for the sake of variety, for which reason they are here inserted.

MENTHA. Tourn. Inst. R. H. 188. tab. 89. Lin. Gen. Plant. 633. [*Mint*, according to the ancients, a goddess, as also according to the poets. The ancients also gave it the name of Sweet-smelling, and where this word is found, this plant is understood. *Mentha* is likewise so called of *Mens*, *Lat.* the mind, because this plant is said to strengthen the mind.] *Mint*; in French, *Menthe*.

The CHARACTERS are,

It hath a lip flower of one petal, sitting on a permanent tubulous empalement of one leaf, which is erect, and cut at the brim into five equal segments. The tube of the petal is a little longer than the empalement. The chaps are cut into four almost equal segments, the upper being a little larger and indented. It hath four awl-shaped stamina, which are erect, standing asunder, the two nearest being longest; they are terminated by roundish summits, and in the bottom of the tube is situated a four-pointed germen, supporting a slender erect style, crowned by a bifid spreading stigma. The germen afterward turns to four naked seeds sitting in the empalement.

This genus of plants is ranged in the first section of Linnæus's fourteenth class, which includes those plants whose flowers have two long and two shorter stamina, and the seeds ripen in the empalement.

The SPECIES are,

1. **MENTHA** (*Viridis*) floribus spicatis, foliis oblongis serratis. Hort. Upsal. 168. *Mint with spiked flowers, and oblong sawed leaves.* *Mentha angustifolia* spicata. C. B. P. 227. *Narrow-leaved spiked Mint, commonly called Spear Mint.*
2. **MENTHA** (*Glabra*) floribus spicatis, foliis longioribus glabris, supernè minimè serratis. *Mint with spiked flowers, and longer smooth leaves, which are very slightly sawed toward their points.* *Mentha angustifolia* spicata glabra. Rand. *Narrow-leaved, smooth, spiked Mint.*
3. **MENTHA** (*Candicans*) foliis lanceolatis serratis, subtus incanis, floribus spicatis hirsutissimis. *Mint with spear-shaped sawed leaves, which are hoary on their under side, and very hairy spiked flowers.* *Mentha Sylvestris* candicans, odore sativi. Doody. Raii Syn. App. *Wild Mint of a white colour, smelling like that of the garden.*
4. **MENTHA** (*Sylvestris*) spicis confertis, foliis serratis tomentosis sessilibus. Hort. Cliff. 306. *Mint with spikes of flowers growing in clusters, and woolly sawed leaves sitting close to the stalks.* *Mentha sylvestris* longiore folio. C. B. P. 227. *Wild Mint with a longer leaf.*
5. **MENTHA** (*Aquatica*) spicis crassioribus, foliis ovato-lanceolatis serratis subtus tomentosis petiolatis. *Mint with thicker spikes, and oval, spear-shaped, sawed leaves, which are woolly on their under side, and have foot-stalks.* *Mentastri* aquatici genus hirsutum, spicâ latiore. J. B. 3. 222. *Hairy Water Mint with a broader spike.*
6. **MENTHA** (*Piperita*) spicis crassioribus interruptis, foliis lanceolatis acutè serratis. *Mint with thicker spikes of flowers, which are interrupted, and spear-shaped leaves which are sharply sawed.* *Mentha fervida nigricans*, piperis sapore. Rand. Hort. Chel. Cat. *Blackish hot Mint with a taste like Pepper, commonly called Pepper Mint.*

7. **MENTHA** (*Crispa*) floribus spicatis, foliis cordatis dentatis undulatis sessilibus. Hort. Cliff. 306. *Mint with spiked flowers, and heart-shaped indented leaves, which are waved, and sit close to the stalks.* *Mentha crispa* Danica sive Germanica speciosa. Mor. Hist. 3. p. 367. *Danish or German curled Mint.*
8. **MENTHA** (*Rotundifolia*) spicis confertis, foliis ovatis rugosis sessilibus. *Mint with spikes growing together, and oval rough leaves sitting close to the stalk.* *Mentastrium folio rugoso rotundiore spontaneum*, flore spicato, odore gravi. J. B. 3. 217. *Wild Mint with a rounder rough leaf, and a spiked flower, having a strong scent.*
9. **MENTHA** (*Rubra*) spicis confertis interruptis, foliis oblongo-ovatis acuminatis dentatis sessilibus. *Mint with interrupted spikes of flowers growing together, and oblong, oval, acute-pointed, indented leaves, sitting close to the stalk.* *Mentha rotundifolia rubra*, aurantii odore. Mor. Hist. 3. 369. *Round-leaved red Mint, smelling like an Orange, commonly called Orange Mint.*
10. **MENTHA** (*Chalepensa*) foliis oblongis dentatis, utrinque tomentosis sessilibus, spicis tenuioribus. *Mint with oblong indented leaves, which are woolly on both sides, set close to the stalk, and very narrow spikes of flowers.* *Mentastrium chalepense*, angustifolium, raro florens. Boerh. Ind. alt. 1. p. 185. *Narrow-leaved wild Mint of Aleppo, which rarely flowers.*
11. **MENTHA** (*Palustris*) floribus capitatis, foliis ovatis serratis petiolatis, staminibus corollâ longioribus. Hort. Cliff. 306. *Mint with flowers growing in heads, oval sawed leaves having foot-stalks, and stamens longer than the petals.* *Mentha rotundifolia palustris* sive aquatica major. C. B. P. 227. *Greater round-leaved Water Mint.*
12. **MENTHA** (*Nigricans*) floribus capitatis, foliis lanceolatis serratis subpetiolatis. Lin. Sp. Plant. 576. *Mint with flowers growing in heads, and spear-shaped sawed leaves with very short foot-stalks.* *Mentha fervida nigricans latifolia*. Rand. *Broad-leaved blackish Pepper Mint.*
13. **MENTHA** (*Arvensis*) floribus verticillatis, foliis ovatis acutis serratis, staminibus corollâ brevioribus. Lin. Sp. Plant. 577. *Mint with flowers growing in whorls, oval, acute, sawed leaves, and stamens shorter than the petals.* *Mentha arvensis*, verticillata hirsuta. J. B. 3. 2. 217. *Whorled hairy field Mint, or Calamint of the shops.*
14. **MENTHA** (*Exigua*) floribus verticillatis, foliis ovatis dentatis, staminibus corollâ longioribus. *Mint with flowers growing in whorls, oval indented leaves, and stamens longer than the petals.* *Mentha aquatica*, exigua. Trag. Lib. 1. c. 6. *Smallest Water Mint.*
15. **MENTHA** (*Gentilis*) floribus verticillatis, foliis ovatis, marginibus ciliatis, staminibus corollam æquantibus. *Mint with whorled flowers, oval leaves whose borders are hairy, and stamens equalling the petals.* *Mentha verticillata*, rotundiore folio, odore ocymi. Dale. *Whorled Mint with a rounder leaf, smelling like Basil.*
16. **MENTHA** (*Hirsuta*) floribus verticillatis, foliis ovatis serratis hirsutis, staminibus corollâ longioribus. *Mint with whorled flowers, oval, sawed, hairy leaves, and stamens longer than the petals.* *Mentha aquatica* sive sisymbrium hirsutum. J. B. 3. 2. 224. *Water Mint, or hairy Sisymbrium.*
17. **MENTHA** (*Verticillata*) floribus verticillatis, foliis lanceolatis acutis serratis, rugosis, staminibus corollam æquantibus. *Mint with whorled flowers, spear-shaped, acute-pointed, sawed, rough leaves, and stamens equalling the petals.* *Mentha verticillata*, longiori acuminato folio, odore aromatico. Rand. Hort. Chel. Cat. *Whorled Mint with a longer acute-pointed leaf, and an aromatic scent.*

There are several other varieties of this genus, which have been found growing naturally in England, of which I have twelve or more in my own collection; but as I suspect some of them to be only accidental variations, arising from the different soils and situations where they have been found, I have not enumerated them all here; those which are here mentioned, I take to be distinct species, having cultivated them more than thirty

thirty years, in which time I have not observed them to change from one to another; several of these I have propagated by seeds, and have found them keep to the kind from which the seeds were sowed.

The first sort is what the gardeners cultivate to supply the markets, and is used both as a culinary herb, and for medicine; it is generally called Spear Mint, and by some Hart Mint; Parkinson and Gerard title it Roman Mint; this is a plant so well known, as to need no description. There are two varieties of this, one with a curled leaf, and the other has variegated leaves, but both these I have had run from the common sort; these are by some preserved in their gardens for the sake of variety, therefore I have mentioned them here.

This herb is greatly esteemed for all disorders of the stomach, loss of appetite, and vomiting; there is a simple water, a spirit, and compound syrup, and a distilled oil of it prepared in the shops.

The second sort hath smoother leaves than the first, and they are rather narrower, in other respects it agrees with that, so that it is frequently cultivated in the gardens for use, without distinction.

The third sort grows naturally in England; the leaves of this are shorter, and broader in the middle than either of the former, the serratures on their edges are more acute, and their under sides are woolly, and very white. The stalks divide more toward the top, so are terminated by a greater number of spikes, the lower part of which are interrupted. The scent of this sort is very like that of the Garden Mint.

The fourth sort hath longer and broader leaves than either of the former, which are woolly and white. The serratures on their edges are farther asunder, and are very sharp pointed; they sit close to the stalks, which are hairy. The spikes of flowers are slender, several of them growing together at the top of the stalk, which are hairy. This is the *Mentastrium*, or wild Mint of the shops, and is an ingredient in the *Trochisci de Myrrha*.

The fifth sort grows naturally in moist places in several parts of England, it is titled Spiked Horse Mint, or Water Mint. The stalks of this are shorter than those of either of the former, and are hairy, as are also the leaves, which are oval, spear-shaped, sawed on their edges, and of a pale colour. The flowers grow in short thick spikes at the top of the stalks, their stamina being shorter than the petal.

The sixth sort is found growing naturally in some parts of England; I have found it by the side of the river between Mitcham and Croydon, in Surry; this hath smooth purple stalks; the leaves are smaller than those of common Mint; they are spear-shaped, sawed on their edges, and of a darker green colour than either of the former; their midrib and veins are purple, and a little hairy on their under side. The spikes of flowers are shorter and thicker than those of the common Mint, and are broken or interrupted at the bottom; they are of a dark purple colour, and their stamina are longer than the petal. The whole plant has a hot biting taste like Pepper, and a pleasant scent. There is a distilled water of this plant kept in the shops, which is by most people preferred to that of the common Mint, for all the purposes which that is usually prescribed, and is esteemed an excellent remedy against the stone and gravel.

The seventh sort was originally brought from Denmark, where it was thought to grow naturally, but Dr. Linnæus fixes it as a native of Siberia. The stalks of this sort are hairy, and rise about the same height with the common. The leaves are heart-shaped, deeply indented on their edges, waved and curled, and sit close to the stalk, they are of a light green. The flowers are purple, growing in thick interrupted spikes at the top of the stalks; their empalements are cut almost to the bottom, and the style of the flower is bifid, standing out beyond the petal.

The eighth sort grows naturally in many parts of

England; this rises with a strong, four-cornered, hairy stalk, about the same height as the common Mint, branching out toward the top, and garnished with oval rough leaves sitting close to the stalks; they are of a dark green, and crenated on their edges. The spikes of flowers grow in clusters at the top of the stalks, which are short and close; the flowers are of an herbaceous white colour, and their stamina are stretched out beyond the petal.

The ninth sort is commonly called Orange Mint, from its scent, which is somewhat like that of the rind of Orange. This rises with an upright smooth stalk about the same height with the common Mint, but does not branch out like that; the leaves are much broader than those of the common sort; the indentures on their edges are deep, and they end in acute points. The spikes of flowers grow in clusters on the top of the stalks, which are interrupted; they are of a pale colour, and their stamina are shorter than the petal. It is commonly cultivated in gardens for its pleasant scent.

The tenth sort grows naturally at Aleppo, but is hardy enough to thrive in the open air in England. This hath slender four-cornered stalks, which are purple at bottom, but woolly upward, seldom branching; they are garnished with oblong indented leaves, which are downy on both sides, sitting close to the stalks. The spikes of flowers are single, and very slender; these do not often appear in England, but when they do it is late in the summer. It creeps much at the root, so the only way to obtain flowers, is to confine their roots in pots.

The eleventh sort grows naturally in ditches in most parts of England, and is commonly known by the name of Water Mint. This hath hairy stalks about a foot high, which branch toward the top, and are garnished with oval sawed leaves, standing upon pretty long foot-stalks. The flowers grow in roundish spikes at the end of the branches; they are of a purple colour, and their stamina are longer than the petal. The whole plant has a very strong scent, somewhat like that of Penny Royal. This sort is sometimes used in medicine, and is reckoned hotter than the Garden Mint: it is carminative, expelling wind out of the stomach, and helping the cholick.

The twelfth sort grows naturally in ditches in several parts of England; the stalks of this are purple, smooth, and short, branching out on every side; the leaves are small, spear-shaped, of a dark colour; they are but slightly sawed on their edges, and stand upon short foot-stalks. The flowers grow in roundish heads on the top of the stalks, they are purple, and their stamina are longer than the petal. This sort has a warm biting taste, but not quite so hot as the Pepper Mint before described, but is often used for it. There is a variety of this which smells like Penny Royal.

The thirteenth sort grows naturally in arable land in most parts of England, and is rarely admitted into gardens. This is the Water Calamint of the shops, but is now seldom used in medicine. The stalks of this sort rise about a foot high and are hairy, garnished with oval leaves ending in acute points, and sawed on their edges. The flowers grow in very thick whorls round the stalks; they are small, of a purple colour, and their stamina are shorter than the petal. The plant has a strong scent like Penny Royal.

The fourteenth sort grows in watery places in many parts of England; this hath weak trailing stalks a foot and a half long, garnished with small oval leaves which are indented on their edges, and stand upon pretty long foot-stalks. The flowers grow in thick whorls round the stalks, they are purple, and their stamina are longer than the petal.

The fifteenth sort grows plentifully on the side of the road between Bocking and Gosfield in Essex; the stalks of this are much smaller, and not so long as those of the former; the leaves are shorter and rounder, and

M E N

are very little indented on their edges, but have their borders set with hairs. The whorls of flowers are smaller, and the whole plant has the scent of Basil.

The sixteenth sort grows naturally in ditches and on the sides of rivers, in many parts of England. This hath hairy four-cornered stalks; which are a foot or more in height; the leaves are oval, sawed, and very hairy. The flowers grow in large whorls toward the top of the stalks; they are purple, and their stamina are longer than the petals. This hath a pleasanter scent than the common Water Mint, so is called Sweet Water Mint by way of distinction: it stands in the list of simples in most dispensaries, but is now seldom used in medicine.

The seventeenth grows naturally by the side of the river Medway, between Rochester and Chatham. This rises with slender hairy stalks near two feet high, garnished with spear-shaped leaves, ending in acute points, which are sawed on their edges; the stalks are beset with whorls of flowers almost their whole length, so that they have frequently ten or twelve whorls on each. The flowers are purplish, and their stamina are equal with the petals; this hath a very pleasant aromatic scent.

All the sorts of Mint are easily propagated by parting the roots in the spring, or by planting cuttings during any of the summer months, but they should have a moist soil; and after the cuttings are planted, if the season should prove dry, they must be often watered until they have taken root; after which, they will require no farther care but to keep them clear from weeds: they should be planted in beds about four feet wide, allowing a path about two feet broad between the beds, to water, weed, and cut the plants. The distance they should be set is four or five inches, or more, because they spread very much at their roots; for which reason, the beds should not stand longer than three years before you plant fresh, for by that time the roots will be matted so closely, as to rot and decay each other, if permitted to stand longer. There are some people who are very fond of Mint fallad in winter and spring; in order to obtain which, they take up the roots before Christmas, and plant them upon a moderate hot-bed pretty close, covering them with fine earth about an inch thick, and cover the bed either with mats or frames of glass. In these beds the Mint will come up in a month's time, and be soon fit to cut for that purpose.

When the herb is cut for medicinal use, it should be done in a very dry season, just when it is in flower; for if it stand longer, it will not be near so handsome, nor so well tasted; and if it be cut when it is wet, it will change black and be little worth; this should be hung up to dry in a shady place, where it may remain until it be used.

If the soil be good in which these plants are set, they will afford three crops every year, but after July they seldom prove good; therefore what shoots are produced after that time should be permitted to remain till Michaelmas, when they must be cut down close; and after having cleared the beds from weeds, you should spread a little fine rich earth all over them, which will greatly encourage the roots against the succeeding spring.

As the distilled water of all the sorts of Mint is esteemed a very wholesome cordial dram, so I should think it might be substituted instead of those vile spirits with which the common people intoxicate themselves; for the Pepper Mint water is as warm on the stomach as any sort of dram, and more so than any of those noxious spirits; and if this was mixed with some other agreeable aromatic herbs, there might certainly be a distilled liquor much more palatable and wholesome than what is now vended in common; for as the generality of the lower class of people are so debauched, as not to be contented without drams, so the less hurtful those are made, the better it will be for the public; and by introducing

M E N

the distilling of herbs, there will be less occasion for using of Wheat.

MENTHA CATARIA. See NEPETA.

MENTZELIA. Plum. Nov. Gen. Plant. 40. tab. 6. Lin. Gen. Plant. 595.

The name was given to this plant by Father Plumier, who discovered it in the French settlements in America, in honour of Dr. Mentzelius, who was physician to the Elector of Brandenburg, and who published an Index of plants in Latin, Greek, and High Dutch.

The CHARACTERS are,

The flower hath a spreading empalement cut into five parts, which sits upon a long cylindrical germen. It hath five petals which spread open, and are a little longer than the empalement, and many erect bristly stamina, terminated by single summits. From the long cylindrical germen which is situated under the flower, arises a bristly style the length of the petals, crowned by a single stigma. The germen afterward turns to a cylindrical long capsule with one cell, containing many small seeds.

This genus of plants is ranged in the first section of Linnaeus's thirteenth class, which includes those plants whose flowers have many stamina and one style.

We know but one SPECIES of this genus, viz.

MENTZELIA (*Aspera*.) Hort. Cliff. 492. Plumier titles it *Mentzelia foliis & fructibus asperis*. Nov. Gen. Plant. 41. *Mentzelia with prickly leaves and fruit.*

This plant grows plentifully at La Vera Cruz, from whence the seeds were sent to England by the late Dr. William Houstoun, which have succeeded in the physic garden at Chelsea.

This plant is annual; it rises with a slender smooth stalk, which is stiff, and becomes a little woody, rising more than three feet high, branching out alternately at distances; the branches are distorted, and run into one another; these are garnished with leaves shaped like the point of an halbert, standing alternately on the branches, upon short foot-stalks; they are covered with short hooded prickles, which fasten themselves into the clothes of those who rub against them; and those parts of the branches easily separate from the plants, and adhere to the clothes in like manner as the seeds of Clivers. The flowers come out singly from the joints of the stalk, resting upon a cylindrical germen, which is near an inch in length, narrow at the base, but widens upward to the top. Upon the top of it comes out the empalement, which is spread open after the same manner as those of the Onagra; then the petals of the flower spread open upon the empalement; they are of a pale yellow colour, and longer than the empalement. In the middle arises a great number of stamina which are erect, and are terminated by single summits; from the germen arises a single style, which is as long as the petals, crowned by a single stigma. The germen afterward turns to a long cylindrical capsule, armed with the like prickles as the leaves, which also fasten themselves to the clothes of those who rub against them; these have but one cell, which is filled with small seeds. As this is an annual plant, which perishes soon after the seeds are ripe, therefore the seeds must be sown on a hot-bed early in the spring, that the plants may be brought forward early in the season, otherwise they will not produce ripe seed in this country. When the plants are come up about an inch high, they should be each transplanted into a separate halfpenny pot filled with light rich earth, and plunged into a hot-bed of tanners bark, being careful to shade them from the sun until they have taken new root; after which time they must be constantly watered every other day in warm weather, and should have fresh air every day admitted to them, in proportion to the warmth of the season, and the heat of the bed in which they are plunged. In about six weeks or two months after transplanting, if the plants have made a good progress, they will have filled the pots with their roots, when they should be shifted into larger pots, which must be filled with light rich earth, and then plunged into the bark-bed in the stove, that they may have room

room to grow in height, observing, as before, to water them duly, as also to admit fresh air to them every day in warm weather: with this management the plants will rise to the height of three feet, and will produce ripe seeds the latter end of August or the beginning of September.

MENYANTHES, is the *Trifolium Palustre*, or Bog Bean.

This plant is common upon boggy places in divers parts of England, but is never cultivated in gardens; for which reason I shall not trouble the reader with any farther account of it, except the taking notice, that this plant is at present in great esteem, being thought an excellent remedy for the rheumatism, gout, and many other disorders. It is frequently called Bog Bean, or Marsh Trefoil, in the markets, and grows plentifully on bogs in many parts of England, where it is gathered and brought to supply the markets.

MERCURIALIS. Tourn. Inst. R. H. 534. tab. 308. Lin. Gen. Plant. 998. [This plant takes its name from Mercury, because the ancients had a notion, that the God Mercury brought this plant into use.] Mercury; in French, *Mercuriale*.

The CHARACTERS are,

It is male and female in different plants; the male flowers have a spreading empalement, which is cut into three concave segments; these have no petals, but have nine or twelve erect hairy stamina, crowned by globular twin summits. The female flowers have no petals, but have two awl-shaped acute-pointed nectariums; to each of these there is a single broad germen, impressed with a furrow between them; these roundish compressed germen have a prickly furrow on each side, and support two reflexed prickly styles, crowned by acute reflexed stigmas. The germen afterward turns to a twin capsule shaped like the scrotum, having two cells, each containing one roundish seed.

This genus of plants is ranged in the eighth section of Linnæus's twenty-second class, which includes those plants whose male flowers grow on different plants from the fruit, and have nine stamina in each.

The SPECIES are,

1. **MERCURIALIS** (*Annua*) caule brachiato, foliis glabris. Hort. Cliff. 461. Mercury with a branching stalk and smooth leaves. *Mercurialis spicata & testiculata* mas & foemina. C. B. P. 121. Mercury with spiked and testiculated flowers, which are both male and female, called French Mercury.
2. **MERCURIALIS** (*Perennis*) caule simplicissimo, foliis scabris. Hort. Cliff. 461. Mercury with a single stalk and rough leaves. *Mercurialis montana spicata & testiculata*. C. B. P. 122. Mountain Mercury, or Dogs Mercury, with spiked and testiculated flowers.
3. **MERCURIALIS** (*Tomentosa*) caule subfruticoso, foliis tomentosis. Hort. Cliff. 461. Mercury with a stalk somewhat shrubby, and woolly leaves. *Mercurialis fruticosa incana, spicata & testiculata*. Tourn. Inst. R. H. 534. Shrubby hoary Mercury, having spiked and testiculated flowers.

The first sort is commonly called French Mercury, from whence it might have been brought into England; for although it is now become a weed in gardens and upon dunghills, yet it is seldom found growing at a distance from habitations. This is an annual plant, with a branching stalk about a foot high, garnished with spear-shaped leaves about an inch and a half long, indented on their edges, of a pale or yellowish green colour. The male plants have spikes of herbaceous flowers growing on the top of the stalks, these fall soon; but the female plants, which have testiculated flowers proceeding from the side of the stalks, are succeeded by seeds, which, if permitted to scatter, will produce plenty of plants of both sexes. The leaves and stalks of this plant are used in medicine, and are reckoned aperitive and mollifying.

The second sort grows under hedges and in woods in most parts of England. This hath a perennial root, which creeps in the ground; the stalks are single and

without branches, rising ten or twelve inches high, garnished with rough leaves, placed by pairs at each joint; they are of a dark green colour, and indented on their edges; these have their male flowers growing in spikes upon different plants, from those which produce seeds.

This hath a poisonous quality, there have been many late instances of it, where people in the spring of the year, when there has been a scarcity of greens, have boiled the leaves of this, and have suffered greatly by eating them.

The third sort grows naturally in the south of France, in Spain, and Italy. This rises with a shrubby branching stalk a foot and a half high, garnished with oval leaves placed by pairs, which are covered with a white down on both sides. The male flowers grow in short spikes from the side of the stalks, upon different plants from the fruit, which are testiculated and hoary. If the seeds of these are permitted to scatter, the plants will come up the following spring; and if the seeds are sown, it should be performed in the autumn, for those which are sown in the spring seldom grow the same year. This plant should have a warm situation and a dry rubbishy soil, in which it will live three or four years, but in hard frost these plants are frequently killed.

MESEMBRYANTHEMUM. Dill. Gen. 9. Hort. Elth. 179. Ficoides. Tourn. Act. R. Par. 1705. Fig Marygold.

The CHARACTERS are,

The flower hath a permanent spreading empalement of one leaf, which is cut at the top into five acute parts. It hath one petal, which is cut into many linear segments almost to the bottom, and ranged in several series, but are joined together at their base; within these are ranged a great number of hairy stamina, terminated by incumbent summits. Under the flower is situated an obtuse five-cornered germen, supporting sometimes five, and often ten or more styles, which are reflexed, and crowned by single stigmas. The germen afterward becomes a roundish fleshy fruit, having as many cells as there are styles, filled with small seeds.

This genus of plants is ranged in the fourth section of Linnæus's twelfth class, which includes those plants whose flowers have from twenty to thirty stamina inserted in the empalement, and five styles.

The SPECIES are,

1. **MESEMBRYANTHEMUM** (*Nodiflorum*) foliis alternis teretiusculis obtusis ciliatis. Hort. Upsal. 129. *Mesembryanthemum* with taper, obtuse, hairy leaves, placed alternately. Ficoides Neapolitana, flore candido. H. L. Fig Marygold of Naples with a white flower, or Egyptian Kali.
2. **MESEMBRYANTHEMUM** (*Crystallinum*) foliis alternis ovatis papulosis undulatis. Hort. Cliff. 216. *Mesembryanthemum* with oval, obtuse, waved leaves placed alternately. Ficoides Africana, folio plantaginis undulato, micis argenteis adperso. Tourn. Act. R. Par. 1705. African Fig Marygold, with a waved Plantain leaf, marked with silvery spots, commonly called the Diamond Ficoides, or Diamond Plant.
3. **MESEMBRYANTHEMUM** (*Geniculiflorum*) foliis semiteretibus papulosis distinctis floribus sessilibus axillariibus. Lin. Sp. Plant. 481. *Mesembryanthemum* with half taper leaves, and flowers sitting close to the wings of the stalks. Ficoides Capense, folio tereti, flore albedo. Pet. Gaz. 78. fol. 3. Fig Marygold of the Cape, with a taper leaf and a whitish flower.
4. **MESEMBRYANTHEMUM** (*Noctiflorum*) foliis semicylindræis, impunctatis distinctis, floribus pedunculatis, calycibus quadrifidis. Lin. Sp. Plant. 481. *Mesembryanthemum* with almost cylindrical leaves, and quadrifid foot-stalks to the flowers. Ficoides Africana, erecta, arborescens, lignosa, flore radiato, primo purpureo, dein argenteo, interdiu clauso, noctu aperto. Boerh. Ind. alt. 1. 290. Upright, ligneous, tree Fig Marygold of Africa, with a radiated flower, which is at first purple, afterward silvery, shut in the day, and open at night.
5. **MESEMBRYANTHEMUM** (*Splendens*) foliis semiteretibus impunctatis recurvis distinctis congestis, calycibus terminalibus

terminalibus digitiformibus. Lin. Sp. 689. *Mesembryanthemum* with taper, unspotted, recurved, distinct leaves in clusters, whose empalement is finger-shaped.

6. MESEMBRYANTHEMUM (*Umbellatum*) foliis subulatis, scabrido-punctatis connatis apice patulo, caule erecto, corymbo trichotoma. Lin. Sp. Plant. 481. *Mesembryanthemum* with awl-shaped leaves which join, having rough spots, an erect stalk, and a corymbus of flowers at the triple division of the stalk. Ficoides Africana erecta teretifolia, floribus albis umbellatis. Par. Bat. 166. Upright African Fig Marygold, with a taper leaf, and white flowers growing in umbels.
7. MESEMBRYANTHEMUM (*Calamiforme*) acaule foliis subteretibus adscendentibus impunctatis connatis, floribus octagynis. Lin. Sp. Plant. 481. *Mesembryanthemum* without a stalk, almost taper leaves which join at their base, and flowers having eight styles. Ficoides Capensis humilis, cepææ folio, flore stamineo. Brad. Suec. p. 10. fol. 19. Low Fig Marygold of the Cape, with an Onion leaf, and a stameneous flower.
8. MESEMBRYANTHEMUM (*Tripolium*) foliis alternis lanceolatis planis impunctatis caulibus laxis simplicibus calycibus pentagonis. Hort. Cliff. 217. *Mesembryanthemum* with plain spear-shaped leaves which are not spotted, a single weak stalk, and a five-cornered empalement. Ficoides Africana, procumbens, tripolii folio, flore argenteo. Hort. Chelf. Trailing African Fig Marygold, with a Tripolium leaf and a silvery flower.
9. MESEMBRYANTHEMUM (*Bellidiflorum*) acaule, foliis triquetris linearibus impunctatis apice trifariam dentatis. Hort. Cliff. 218. *Mesembryanthemum* without a stalk, having narrow, three-cornered, unspotted leaves, marked with three indentures at their points. Ficoides Capensis humilis, folio triangulari in summitatem dentato, flore minore purpurascens. Brad. Suec. p. 9. tab. 18. Dwarf Marygold of the Cape, with a triangular leaf indented at the top, and a smaller purplish flower.
10. MESEMBRYANTHEMUM (*Subulatum*) acaule foliis subulatis triquetris dorso supernè ferratis. *Mesembryanthemum* without a stalk, and awl-shaped three-cornered leaves, whose back part is sawed toward the top.
11. MESEMBRYANTHEMUM (*Deltoides*) foliis deltoidibus triquetris dentatis impunctatis distinctis. Hort. Cliff. 218. *Mesembryanthemum* with three-cornered indented leaves, which are shaped like the Greek delta, without spots, and distinct. Ficoides Africana, folio triangulari crasso, brevi, glauco, ad tres margines aculeato. Boerh. Ind. alt. 1. 290. African Fig Marygold, with a short, thick, gray, triangular leaf, with prickles on the three edges.
12. MESEMBRYANTHEMUM (*Caulescens*) caulescens, foliis deltoidibus, lateribus minimè dentatis. Stalky *Mesembryanthemum*, with leaves shaped like the Greek delta, whose sides are a little indented. Ficoides Africana, folio triangulari glauco, brevissimo, crassissimo, margine non spinoso. Boerh. Ind. alt. 1. 290. African Fig Marygold, with very thick, short, triangular, gray leaves, having no spines on their edges.
13. MESEMBRYANTHEMUM (*Barbatum*) foliis subovatis papulosis distinctis apice barbatis. Hort. Cliff. 216. *Mesembryanthemum* with almost oval leaves, having distinct bladders bearded at their points. Ficoides seu ficus aizoides Africana, folio variegato aspero, ad apicem stella spinosa armato. Boerh. Ind. alt. 1. p. 291. African Fig Marygold, with a rough variegated leaf, whose point is armed with spines in form of a star.
14. MESEMBRYANTHEMUM (*Stellatum*) caulibus decumbentibus, foliis teretibus papulosis apice barbatis. *Mesembryanthemum* with decumbent stalks and taper bladdered leaves, whose points are bearded like a star. Ficoides Capensis frutescens, folio tumido, extremitate stellatâ, flore purpureo. Brad. Suec. Dec. 1. tab. 6. Shrubby Fig Marygold of the Cape, with a star-pointed tumid leaf, and a purple flower.
15. MESEMBRYANTHEMUM (*Hispidum*) foliis cylindricis papulosis distinctis, caule hispido. Lin. Sp. Plant. 482. *Mesembryanthemum* with a prickly stalk, and deflexed cylindrical leaves with pulpy bladders. Ficoides Afra, fruticosa, caule lanugine argenteâ ornato, folio tereti, parvo, longo, guttulis argenteis quasi scabro, flore vi-

olaceo. Boerh. Ind. alt. 1. 291. African shrubby Fig Marygold, having stalks adorned with silvery down, and long, small, taper leaves, spotted as it were with silvery drops, and a Violet-coloured flower.

16. MESEMBRYANTHEMUM (*Villosum*) caule foliisque pubescentibus. Hort. Cliff. 217. *Mesembryanthemum* whose stalks and leaves are garnished with downy hairs.
17. MESEMBRYANTHEMUM (*Scabrum*) foliis subulatis distinctis subtus undique muricatis, calycibus muticis. Hort. Cliff. 219. *Mesembryanthemum* with awl-shaped leaves, which are distinct, every where rough on their under side, and chaffy empalements. Ficoides Afra, folio triangulari viridi longo aspero, flore violaceo. Boerh. Ind. alt. 290. African Fig Marygold, with a long, green, rough, triangular leaf, and a Violet-coloured flower.
18. MESEMBRYANTHEMUM (*Uncinatum*) articulis caulinis terminatis in folia connata acuminata subtus dentata. Hort. Cliff. 218. *Mesembryanthemum* whose joints of the stalks are terminated by acute-pointed leaves, which are joined at their base, and indented on their under side. Ficoides Afra, folio triangulari glauco, perfoliato, brevissimo, apice spinoso. Boerh. Ind. alt. 290. African Fig Marygold, with a short, perfoliated, triangular leaf, whose point is prickly, commonly called Buckhorn Ficoides.
19. MESEMBRYANTHEMUM (*Perfoliatum*) perfoliatum, foliis majoribus, apicibus triacanthis. Hort. Elth. 251. Perfoliate *Mesembryanthemum* with larger leaves, whose points have three thorns. Ficoides Africana frutescens perfoliata, folio triangulari glauco punctato, cortice lignoso candido tenui. Tourn. Act. Par. 1705. Shrubby, perfoliate, African, Fig Marygold, with a triangular, gray, spotted leaf, and a thin, white, lincous bark, commonly called Stagshorn Ficoides.
20. MESEMBRYANTHEMUM (*Spinosum*) foliis tereti-triquetris punctatis distinctis spinis ramosis. Hort. Cliff. 216. *Mesembryanthemum* with taper three-cornered leaves, which have distinct spots and branching spines. Ficoides Africana, aculeis longissimis & foliolis nascentibus ex foliorum alis. Tourn. Act. R. Par. 1705. African Fig Marygold with long spines, and smaller leaves arising from the wings of the leaves.
21. MESEMBRYANTHEMUM (*Tuberosum*) foliis subulatis papulosis, distinctis apice patulis radice capitata. Hort. Cliff. 216. *Mesembryanthemum* with awl-shaped pimply leaves, and a beaded root. Ficoides Africana, folio triangulari recurvo, floribus umbellatis obsoleti coloris, externè purpureis. Tourn. Act. Par. 1705. African Fig Marygold with a triangular recurved leaf, and umbellated flowers of a dark colour, which are purple on their outside.
22. MESEMBRYANTHEMUM (*Tenuifolium*) foliis subulatis semiteretibus glabris, distinctis internodio longioribus. Hort. Cliff. 216. *Mesembryanthemum* with awl-shaped, half-taper, smooth, distinct leaves, whose joints are farther distant. Ficoides Capensis humilis, teretifolia, flore coccineo. Brad. Suec. p. 13. Low Fig Marygold of the Cape, with a taper leaf and a scarlet flower.
23. MESEMBRYANTHEMUM (*Stipulaceum*) foliis subtriquetris compressis incurvatis punctatis distinctis congestis basi marginatis. Lin. Sp. 693. *Mesembryanthemum* with three-cornered, compressed, incurved leaves, having distinct spots, whose base are bordered and clustered. *Mesembryanthemum* frutescens, flore purpureo rariore. Hort. Elth. tab. 209.
24. MESEMBRYANTHEMUM (*Crassifolium*) foliis semicylindricis impunctatis connatis, apice triquetris caule repente semicylindricis. Hort. Cliff. 217. *Mesembryanthemum* with a creeping cylindrical stalk, cylindrical smooth leaves, joining at their base, whose points are three-cornered. Ficoides Africana reptans, folio triangulari, flore saturatè purpureo. Brad. Suec. p. 16. tab. 38. Creeping African Fig Marygold with a green triangular leaf, and deep purple-coloured flower.
25. MESEMBRYANTHEMUM (*Falcatum*) foliis sub-acinaciformibus incurvis punctatis distinctis ramis teretibus. Hort. Cliff. 219. *Mesembryanthemum* with distinct, smooth, falchion-shaped leaves, and taper branches. Ficoides Afra folio triangulari ensiformi brevissimo, flore

- flore dilute purpurascens filamentosa. Brad. Suec. Dec. 5. tab. 42. *African Fig Marygold with a triangular, cimeter-shaped, short leaf, and a pale purplish flower.*
26. MESEMBRYANTHEMUM (*Glomeratum*) foliis teretiusculis compressis punctatis, caule paniculato multifloro. Lin. Sp. 694. *Mesembryanthemum with taper, compressed, spotted leaves, and a panicled stalk with many flowers. Mesembryanthemum falcatum minus, flore carneo minore. Hort. Elth. tab. 213.*
27. MESEMBRYANTHEMUM (*Edule*) foliis æquilateri-triquetris acutis strictis impunctatis connatis carina subferratis, caule ancipiti. Lin. Sp. 695. *Mesembryanthemum with equilateral, acute, unspotted leaves joined at their base, whose keel are sawed. Ficoides seu ficus aizoides Africana major procumbens, triangulari folio, fructu maximo eduli. H. L. 244. Greater trailing African Fig Marygold, with a triangular leaf and a large eatable fruit.*
28. MESEMBRYANTHEMUM (*Bicolorum*) foliis subulatis lævibus punctatis distinctis caule frutescente corollis bicoloribus. Lin. Sp. Plant. 695. *Mesembryanthemum with awl-shaped smooth leaves, which have different spots, a shrubby stalk, and the flower of two colours. Ficoides Capensis frutescens, folio tereti punctato, petalis luteis. Brad. Suec. i. p. 8. tab. 7. Shrubby Fig Marygold of the Cape, with a taper leaf having punctures, and yellow petals.*
29. MESEMBRYANTHEMUM (*Acinaciforme*) foliis acinaciformibus impunctatis connatis, angulo carinali scabris, petalis lanceolatis. Lin. Sp. 695. *Mesembryanthemum with sharp, three-cornered, unspotted leaves, joined at their base, whose keel are rough, and spear-shaped petals of the flower. Ficoides Africana folio longo triangulari incurvo, caule purpureo. Tourn. Act. Par. 1705. African Fig Marygold with a long triangular leaf, which is incurved, and a purple stalk.*
30. MESEMBRYANTHEMUM (*Loreum*) foliis semicylindricis recurvis congestis basi interiore gibbis connatis, caule pendulo. Lin. Sp. 694. *Mesembryanthemum with cylindrical recurved leaves, whose base are clustered and join, and a pendulous stalk. Mesembryanthemum loreum. Hort. Elth. tab. 200.*
31. MESEMBRYANTHEMUM (*Serratum*) foliis subulatis triquetris punctatis distinctis angulo carinali retrorsum ferratis. Lin. Sp. 696. *Mesembryanthemum with awl-shaped leaves having distinct spots, and the angle of the keel sawed. Mesembryanthemum serratum flore acetabuliformi luteo. Hort. Elth. tab. 192.*
32. MESEMBRYANTHEMUM (*Tuberculatum*) acaule foliis semicylindricis connatis externè tuberculatis. Hort. Cliff. 219. *Mesembryanthemum without a stalk, and cylindrical leaves which have tubercles on their outsides, and are joined at their base. Ficoides Afra, folio triangulari, longo, succulento, caulibus rubris. Boerh. Ind. alt. 290. African Fig Marygold with a long, triangular, succulent leaf, and red stalks.*
33. MESEMBRYANTHEMUM (*Veruculatum*) foliis triquetra-cylindricis acutis connatis arcuatis impunctatis distinctis. Hort. Cliff. 220. *Mesembryanthemum with three-cornered cylindrical leaves which are connected at their base, bowed and smooth. Ficoides Afra arborecens, folio tereti glauco, apice purpureo crasso. Boerh. Ind. alt. 291. African Tree Fig Marygold, with a taper gray leaf, having a thick purple top.*
34. MESEMBRYANTHEMUM (*Glaucum*) foliis triquetris acutis, punctatis distinctis calycinis foliolis ovato-cordatis. Lin. 42. MESEMBRYANTHEMUM (*Difforme*) foliis difformibus punctatis connatis. Prod. Leyd. 287. *Mesembryanthemum with deformed leaves. Ficoides Afra foliis latissimis crassimis lucidis, difformibus. Boerh. Ind. alt. 292. African Fig Marygold, with very broad, thick, shining, deformed leaves.*
43. MESEMBRYANTHEMUM (*Lucidum*) acaule foliis linguiformibus lucidis imarginatis. *Mesembryanthemum without a stalk, and tongue-shaped lucid leaves, indented at the top. Ficoides Afra acaulos, foliis latissimis crassimis lucidis conjugatis, flore aureo amplissimo. Tourn. Acad. R. Scien. 1705. African Fig Marygold without a stalk, broad, thick, shining leaves growing by pairs, and a very large yellow flower.*
44. MESEMBRYANTHEMUM (*Linguiforme*) acaule foliis linguiformibus altero margine crassioribus impunctatis. Lin. Sp. 699. *Mesembryanthemum without a stalk, very broad tongue-shaped leaves, one edge being thicker than the other, and without spots. Ficoides Afra acaulos, foliis latissimis crassissimis, lucidis conjugatis, flore aureo amplo, pedunculo brevi. Boerh. Ind. alt. 292. African Fig Marygold having no stalk, very broad, thick, shining leaves placed by pairs, and a large golden flower with a short foot-stalk.*
45. MESEMBRYANTHEMUM (*Albidum*) acaule foliis triquetris. *Mesembryanthemum having no stalk, and gray, entire, three-cornered leaves. Mesembryanthemum foliis robustis albicantibus. Hort. Elth. 243. Mesembryanthemum with strong whitish leaves.*

46. MESEMBRYANTHEMUM (*Pugioneforme*) foliis alternis subulatis triquetris longissimis impunctatis. Hort. Cliff. 216. *Mesembryanthemum with alternate, awl-shaped, three-cornered leaves, which are very long, without spots. Ficoides Capensis, caryophylli folio, flore aureo specioso. Brad. Suec. Dec. 2. p. 5. tab. 14. Fig Marygold of the Cape, with a Clove Gilliflower leaf, and a beautiful golden-coloured flower.*

These plants are most of them natives of the Cape of Good Hope, from whence their seeds were first brought to Holland, and the plants raised in many of their curious gardens, and have since been communicated to most parts of Europe; these were at first titled Chrysanthemum by the old botanists, but afterward they were titled Ficoides by Herman and Tournetfort, from their capsules being shaped like little Figs; afterward they had this title of Mesembryanthemum applied to them, which signifies a flower opening in the middle of the day, which is what most of the species do; there are three or four of them which open in the evening, and are closed all the day; these have been separated from the others by some, and have had the title of Nycteranthemum applied to them, from their flowers being expanded in the night; but as they all agree in the characters which distinguish the genus, they should by no means be separated.

Most of the plants of this genus have beautiful flowers, which appear at different seasons of the year; some of them flower early in the spring, others in summer, some in the autumn; and there are others which flower in winter; and many of them produce their flowers in such quantity, as that when they are expanded, the plants are entirely covered with them; they have all of them thick succulent leaves, but some of the species are much more so than others, and the figures of their leaves vary so much in the several species, that they afford an agreeable variety when they are not in flower.

To describe all the species which are here mentioned, would swell this work too much, and as their titles are short descriptions of the species, I shall not enlarge more on that head, but proceed to their culture. All the sorts here mentioned are perennial plants except the two first, which are annual. The perennial sorts are easily propagated by cuttings during any of the summer months; such of them as have shrubby stalks and branches, very readily take root when planted in a bed of light soil, and covered either with mats or glasses, but when they are covered with the latter, they must be shaded every day when the sun is warm; these cuttings of the shrubby sorts need not be cut from the plant more than five or six days before they are planted, during which time they should be laid in a dry room, not too much exposed to the sun, that the part which was separated from the old plants may heal over and dry before they are planted, otherwise they are apt to rot; these may be planted at about three inches distance from each other, and the earth pressed close to them, but none of their leaves should be buried in the ground, for as they abound with moisture, so if they are covered with the earth, it will cause them to rot, and that often destroys the cuttings; therefore when the cuttings are taken from the old plants, they should be divested of their lower leaves, so far as may be necessary, to allow a naked stalk of sufficient length for planting.

When the cuttings are planted, it will be necessary to give them a little water, to settle the ground about them, but it should be done with caution, for too much wet will spoil them; if these are shaded every day from nine or ten o'clock till three or four, when the sun is warm, it will prevent the ground from drying too fast, so that the cuttings need not be watered oftener than once in a week; but if there should happen some gentle showers of rain, it will be proper to take off their covers, and let them receive it, but they should be screened from hard rains. The cuttings thus managed will have put out good roots in

about six weeks, when they should be carefully taken up, and each planted in a separate small pot filled with light sandy earth, and then placed in a shady situation, giving them a little water to settle the earth to their roots; in this place they may remain about ten days or a fortnight, by which time they will have taken good root, and may be removed to a sheltered place, where they may have more sun, in which they may remain till autumn; during the summer months, these may be watered twice, or in very hot weather, three times a week, but it must not be given them in too great plenty; but as the sun declines in autumn, they should not have it oftener than once a week, for if they are often supplied with it, the plants will grow luxuriant; their leaves and branches will be so replete with moisture, that the early frosts in the autumn will destroy them; whereas when they are kept dry, their growth will be stunted; so that they will be hardy enough to resist small frosts, but there must be care taken that they do not shoot their roots through the holes of the pots into the ground, for when they do, the plants will grow very luxuriant; and when the pots are removed, and those roots are torn off, their leaves and branches will shrink, so will not recover it in a long time, if ever; to prevent which, the pots should be removed every fortnight, and where the roots are beginning to come through the pots, they should be cut off. The sorts which grow very freely should be shifted three times in the summer, to pare off their roots, and keep them within compass, and these should never be planted in rich earth for the reasons before given; for if the earth is fresh, there will require no dung or other compost, unless it is strong, in which case sea sand, or lime rubbish, will be a good mixture; the quantity of either must be in proportion to the stiffness of the ground, always being careful to render it so light, as that the wet may easily pass off.

We next proceed to treat of those sorts, whose stalks and leaves are very succulent. The cuttings of these should be taken from the plants ten days or a fortnight before they are planted, that they may have time for their wounded part to heal over and dry; the lower leaves of these should also be stripped off, that their naked stalks may be of a sufficient length for planting. As these are mostly plants of humble growth, so if their stalks are divested of their leaves an inch and a half, it will be sufficient. The cuttings of these sorts require to be covered with glasses, to keep off the wet; they must also have less water than the other, but in other particulars require the same treatment. The roots of these do not spread and extend so much as those of the other, so will not require to be shifted oftener than twice a year at most; they must also be kept in small pots to confine their roots; the earth in which they are planted should be rather light and not rich. During the summer season they must not have too much wet, and in the winter they must have but little water. If these succulent sorts are placed in an open airy glass-case in winter, where they may have free air admitted to them in plenty in mild weather, and screened from the frost, they will thrive much better than when they are more tenderly treated. The other shrubby kinds may be sheltered in winter under a common frame, where, if they are protected from frost and wet, it is all they require; for the hardier these are treated, the greater quantity of flowers they will produce: and some of the sorts are so hardy, as to live abroad when planted close to a good aspect wall, and in a poor dry soil; so that where there is room to dispose them against a wall, and the border is raised with lime rubbish to prevent their rooting deep and growing luxuriant, they may be preserved through the winter with very little shelter, and these will flower much better than those under cover.

The first sort grows naturally in Egypt, where they cut up the plants, and burn them for pot-ash; and this is esteemed as the best sort for making hard sope, and the best sort of glass.

M E S

This is an annual plant, which does not perfect seeds in England; for when it is placed in the stove, or kept in the hot-bed, their stalks grow long and slender, so are not productive of flowers; and those which are raised in hot-beds, and afterward exposed in the open air, will flower pretty freely, but do not perfect their seeds. As this plant will thrive in South Carolina as well as in its native soil, so it might turn to the advantage of that colony, and likewise become beneficial to the public, if the inhabitants could be prevailed on to cultivate this plant.

The second sort is annual; this is a native at the Cape of Good Hope. It is propagated for the oddness of its leaves and stalks, which are closely covered over with pellucid pimples full of moisture, which, when the sun shines on the plants, they reflect the light, and appear like small bubbles of ice; from whence some have called it the Ice Plant, and others have named it the Diamond Plant, or Diamond Ficoides.

This sort is propagated by seeds, which must be sown on a hot-bed early in the spring; and when the plants come up, they must be planted on a fresh hot-bed to bring them forward; after they have taken root in the hot-bed, they should have but little wet, for moisture will rot them. When they are grown large enough to transplant again, they should be each planted into a small pot, filled with light fresh earth, but not rich, and plunged into a hot-bed of tan, observing to shade them in the heat of the day until they have taken new root; then they should have plenty of fresh air admitted to them every day in warm weather, to prevent their drawing weak. In the latter end of June, some of the plants may be inured to bear the open air, and afterward they may be turned out of the pots, and planted into a warm border, where they will thrive, and spread their branches to a great distance upon the ground; but these plants will not be very productive of flowers, therefore some of them must be continued in the small pots, and may at the same time, when the others are planted out, be removed into the stove or glass-case, placing them upon the shelves, that the roots may not get out from the bottom of the pots, so that they may be confined, which will cause them to flower plentifully, and from these good seeds may every year be obtained.

MESPILUS [*Μέσπιλος*, Gr.] Tourn. Inst. R. H. 641. tab. 410. Lin. Gen. Plant. 549. *The Medlar*.

The CHARACTERS are,

The empalement of the flower is permanent, of one leaf, cut into five spreading concave segments. The flower is composed of five roundish concave petals, which are inserted in the empalement. The number of stamina are different in the several species, from ten to twenty or more, these are also inserted in the empalement, and are terminated by single summits. The germen is situated under the flower, and supports an uncertain number of styles from three to five, which are crowned by beaded stigmas. The germen afterward becomes a roundish or oval berry, carrying the empalement on its top, and inclosing four or five hard seeds.

This genus of plants is ranged in the fourth section of Linnæus's twelfth class, which includes the plants whose flowers have twenty stamina inserted to the empalement, and five styles.

The SPECIES are,

1. **MESPILUS** (*Sylvestris*) inermis, foliis lanceolatis dentatis acuminatis, subtus tomentosis, calycibus acuminatis. *Smooth Medlar, with spear-shaped, acute-pointed, indented leaves, woolly on their under side, and acute-pointed empalements.* Mespilus folio laurino major, fructu minori, rariori substantiâ. Hort. Cath. *Greater Medlar with a Bay-tree leaf, and a smaller less substantial fruit.*
2. **MESPILUS** (*Germanica*) inermis foliis lanceolatis integerrimis subtus tomentosis, calycibus acuminatis. Hort. Cliff. 189. *Unarmed Medlar with spear-shaped entire leaves, which are downy on their under side, and acute-pointed empalements.* Mespilus Germanica, folio laurino, non ferrato, sive Mespilus sylvestris. C. B.

M E S

P. 453. *German Medlar with a Bay-tree leaf which is not sawed, or wild Medlar.*

3. **MESPILUS** (*Pyracantha*) spinosa, foliis lanceolato-ovatis crenatis, calycibus fructibus obtusis. Hort. Cliff. 189. *Prickly Medlar, with spear-shaped, oval, crenated leaves, and obtuse empalements to the fruit.* Mespilus aculeata, amygdali folio. Tourn. Inst. 642. *Prickly Medlar with an Almond leaf, called Pyracantha.*
4. **MESPILUS** (*Cordato*) foliis cordata-ovatis acuminatis, acutè ferratis, ramis spinosis. Fig. Plant. tab. 179. *Medlar with heart-shaped, oval, acute-pointed leaves, which are sharply sawed, and prickly branches.*
5. **MESPILUS** (*Amelanchier*) inermis, foliis ovalibus serratis, cauliculis hirsutis. Lin. Sp. Plant. 478. *Medlar without thorns, having oval sawed leaves, and hairy stalks.* Mespilus folio rotundiori, fructu nigro subdulci. Tourn. Inst. 642. *Medlar with a rounder leaf and a black sweetish fruit, commonly called Amelanchier.*
6. **MESPILUS** (*Canadensis*) foliis ovato-oblongis glabris ferratis, caule inermi. Lin. Sp. Plant. 478. *Medlar with oval, oblong, smooth, sawed leaves, and branches without thorns.* Mespilus inermis, foliis subtus glabris obversè-ovatis. Flor. Virg. 54. *Medlar without thorns, and obverse oval leaves, which are smooth on their under side.*
7. **MESPILUS** (*Cotoneaster*) foliis ovatis integerrimis. Hort. Cliff. 189. *Medlar with oval entire leaves.* Mespilus folio subrotundo, fructu rubro. Tourn. Inst. R. H. 642. *Medlar with a roundish leaf and a red fruit, commonly called Dwarf Quince.*
8. **MESPILUS** (*Chamaespilus*) inermis, foliis ovalibus ferratis glabris, floribus capitatis, bracteis deciduis linearibus. Lin. Sp. Plant. 479. *Medlar without thorns, having smooth, oval, sawed leaves, beaded flowers, and linear bractee which fall off.* Cotoneaster folio oblongo ferrato. C. B. P. 452. *Bastard Quince with an oblong sawed leaf.*
9. **MESPILUS** (*Orientalis*) foliis ovatis crassis integerrimis, subtus tomentosis, floribus umbellatis axillariibus. *Medlar with oval, thick, entire leaves, which are woolly on their under side, and flowers growing in umbels from the wings of the stalk.* Chamaecerasus Idæa. Alp. Exot. 5. *Dwarf Cherry of Mount Ida.*
10. **MESPILUS** (*Arbutifolia*) inermis, foliis lanceolatis crenatis subtus tomentosis. Hort. Cliff. 189. *Virginia Medlar with an Arbutus leaf.* Mespilus Virginiana, folio arbuti. H. L. 578.
11. **MESPILUS** (*Virginiana*) inermis, foliis oblongo-ovatis, subtus tomentosis, fructu ovato, pedunculis longissimis. *Smooth Virginia Medlar, with oblong oval leaves, downy on their under side, and oval fruit on long foot-stalks.*

The first sort grows naturally in Sicily, where it becomes a large tree; this rises with a straiter stem, and the branches grow more upright than those of the Dutch Medlar; the leaves are narrower and not sawed on their edges; the flowers are smaller than those of the Dutch Medlar, and the fruit is shaped like a Pear.

The second sort is generally called the Dutch Medlar; this never rises with an upright stalk, but sends out crooked deformed branches at a small height from the ground; the leaves of this are very large, entire, and downy on their under side. The flowers are very large, as are also the fruit, which are rounder, and approach nearer to the shape of an Apple. This being the largest fruit, is now generally cultivated in the gardens; but there is one with smaller fruit, which is called the Nottingham Medlar, of a much quicker and more poignant taste than this; which is, I suppose, only a variety, so I have not enumerated it as a distinct species.

The fifth sort grows naturally in Austria, Italy, and France, particularly near Fontainebleau; this rises with many slender stalks about three or four feet high, which put out small side branches, covered with a dark purple bark, having no thorns, closely garnished with oval leaves, about three quarters of an inch long, and half an inch broad, slightly sawed on their edges; the small side branches which sustain the flowers,

M E S

flowers, are very hairy and woolly, as are also the foot-stalks, and the under side of the leaves, but their upper sides are smooth and green. The flowers come out in bunches at the end of the shoots, which have five long narrow petals, and about ten stamina in each. The flowers are succeeded by small fruit, which, when ripe, are black; the gardeners call this New England Quince; there is one of this kind which grows naturally in North America, but the leaves of that are wedge-shaped and not sawed on the edges, so I take it to be a different species.

The sixth sort grows naturally in Canada; this is also a low shrub, seldom rising more than five feet high, dividing into several smooth branches, covered with a purplish bark. The leaves grow upon long slender foot-stalks; they are one inch and a half long, and an inch broad, smooth on both sides, and a little sawed on their edges. The flowers come out in small bunches at the end of the branches; they are about the size of those of the common Hawthorn, and are succeeded by small fruit of a purplish colour when ripe.

The seventh sort grows naturally on the Pyrenean mountains, and in other cold parts of Europe; this rises with a smooth shrubby stalk about four feet high, dividing into a few small branches, which are covered with a purple bark, and garnished with oval entire leaves, little more than one inch long, and about three quarters of an inch broad, having very short foot-stalks. The flowers come out from the side of the stalks, two or three together; they are small, of a purplish colour, and sit close to the stalks; these appear in May, and are succeeded by small roundish fruit, which are of a bright red colour when ripe.

The eighth sort grows naturally in the northern parts of Europe; this hath a smooth stalk, rising about four or five feet high, sending out slender branches, which are covered with a purplish bark, and garnished with oval smooth leaves about two inches long, and one inch and a half broad, sawed on their edges, but the teeth point upward; they have pretty long slender foot-stalks, and are of a yellowish green on both sides. The flowers come out from the wings of the stalk, four or five joined together in a close head, of a purplish colour; between the flowers come out long narrow bractea, which are purplish, and fall off as the flowers begin to decay. The fruit is small, and red when ripe.

The ninth sort grows naturally upon mount Ida, in Crete, where the poor shepherds feed upon the fruit when ripe; this hath a smooth stalk about eight feet high, dividing into many smooth branches, garnished with oval leaves two inches and a half long, and near two inches broad, of a thick substance, and a dark green on their upper side, but downy on their under, standing upon short foot-stalks. The flowers come out from the side of the stalk upon short small branches, five or six growing upon each in a close bunch; they are of a purple colour, the petals being but little longer than the empalement, which is woolly, and cut into five obtuse segments. The fruit is large, roundish, and of a fine red colour when ripe.

The tenth sort grows naturally in North America, where it rarely rises more than five feet high, sending out a few upright branches, garnished with spear-shaped leaves whose edges are crenated, and their under side downy; the flowers are produced in small bunches on the side, and at the extremity of the branches, which are succeeded by small roundish fruit a little compressed, of a purple colour when ripe.

The eleventh sort is an inhabitant of the same country with the former; this rises six or eight feet high, sending out side branches, garnished with oblong, oval, entire leaves, downy on their under side; the flowers are produced in small bunches, standing on long foot-stalks, having each five narrow white petals which are contracted at their base, and are succeeded by oval fruit of a blue colour when ripe, and

M I C

are by some of the inhabitants of America eaten in a scarcity of other sorts of fruit, but are not very palatable.

All these sorts are hardy enough to thrive in the open air in England, and some of them are very ornamental plants for gardens, where, during the season of their flowering, they will make a fine appearance; and again, in autumn, when their fruit are ripe, they will afford an agreeable variety, and their fruit will be food for the deer and birds; so that if clumps of each sort are planted in different parts of the garden, nothing can be more ornamental.

The American kinds are usually propagated in the nurseries, by grafting or budding them upon the common White Thorn, but the plants so propagated will never grow to half the size of those which are propagated by seeds; so that those plants should always be chosen which have not been grafted or budded, but are upon their own roots.

But there are many who object to this method of raising the plants from seeds, on account of their seeds not growing the first year, as also from the tediousness of the plant's growth after; but where a person can furnish himself with the fruit in autumn, and take out their seeds soon after they are ripe, putting them into the ground immediately, the plants will come up the following spring, if they are kept clean from weeds, and in very dry weather supplied with water, they will make good progress; but if they are planted in the places where they are to remain, after two years growth from seeds, they will succeed much better than when the plants are of greater age; the ground should be well trenched, and cleansed from the roots of all bad weeds. The best time to transplant them is in autumn, when their leaves fall off; these should be constantly kept clean from weeds, and if the ground between the plants is dug every winter, it will greatly encourage the growth of the plants, so that if they are cleaned three or four times in the summer, it will be sufficient.

All the sorts of *Mespilus* and *Crataegus* will take, by budding or grafting upon each other; they will also take upon the Quince, or Pear stocks, and both these will take upon the Medlars; so that these have great affinity with each other, and might be with more propriety brought together under the same genus, than the Pear and Apple, which will not take upon each other; but although the Pear will take upon the White Thorn, yet it is not adviseable to make use of these stocks, because they generally cause the fruit to be small and often to crack, and renders their flesh stony; so unless it is the very soft melting kinds of Pears which are upon these stocks, the fruit will not be good.

MICROPUS. Lin. Gen. Plant. 892. Gnaphalodes. Tourn. Inst. R. H. 439. tab. 261. Bastard Cudweed.

The CHARACTERS are,

It hath hermaphrodite and female flowers, which are included in the same double empalement; there are ten hermaphrodite flowers which compose the disk; these have one petal, are funnel-shaped, erect, and cut into five parts at the top, and have five short bristly stamina, terminated by cylindrical summits, with an obsolete germen supporting a short slender style, crowned by an obsolete stigma. In the same empalement are five female flowers in the circumference, which have each an oval germen which is compressed, hid under the scales of the interior empalement, each having a style by their side, which is bristly, turning toward the hermaphrodite flowers, crowned by slender acute-pointed stigmas, divided in two parts. The female flowers have each a single oval seed succeeding them, included in the small leaves of the empalement, but the hermaphrodite flowers are barren.

This genus of plants is ranged in the fourth section of Linnæus's nineteenth class, which includes those plants whose flowers are composed of female fruitful flowers

M I L

flowers in the border, and barren hermaphrodite flowers in the middle.

We have but one SPECIES of this genus in the English gardens, viz.

MICROPUS (*Supinus*) caule prostrato, foliis geminis. Hort. Upsal. 275. Prod. Leyd. 145. *Micropus, or Bastard Gnaphalium, with a trailing stalk.* Gnaphalodes Lusitana. Tourn. Inst. R. H. 439. *Portugal Bastard Cudweed.* This is an annual plant, which grows naturally in Portugal, near the sea. The roots send out several trailing stalks about six or eight inches long, garnished with small, oval, silvery leaves, whose base embrace the stalks. The flowers come out from the wings of the stalks in small clusters; they are very small, white, and sit in a double empalement, the interior being so large, as to almost hide the flowers. It flowers in June and July, and the seeds ripen in autumn; this is frequently preserved in gardens for the beauty of its silvery leaves: if the seeds are sown in autumn, or are permitted to scatter, the plants will come up in the spring, and will require no other care but to keep them clean from weeds, and thin them where they are too close. When the seeds of this plant are sown in the spring, they seldom grow the first year.

MICROSCOPE, a dioptrical instrument, by means of which very minute or small objects are represented very large, and capable of being viewed very distinctly, according to the laws of refraction.

This instrument may be of singular use to a curious enquirer into the operation of vegetative nature, by viewing nicely the several minute vessels and parts of vegetables, in order to discover their various uses, and how the business of vegetation is carried on, as also to examine the minute parts of flowers, which are not obvious to the naked eye.

MILDEW is a disease that happens to plants, and is supposed to be caused by a dewy moisture which falls on them, and continuing, for want of the sun's heat to draw it up, and by its acrimony corrodes, gnaws, and spoils the inmost substance of the plant, and hinders the circulation of the nutritive sap, upon which the leaves begin to fade, and the blossoms and fruit are much prejudiced: but Mildew is rather a concrete substance, which exudes through the pores of the leaves.

However, what the gardeners commonly call Mildew, is an insect, which is frequently found in great plenty, preying upon this exudation.

Others say, That Mildew is a thick clammy vapour, exhaled in the spring and summer from plants, blossoms, and even the earth itself, in close still weather, where there is neither sun enough to draw it upwards to any considerable height, nor wind of force strong enough to disperse it, and that, hanging in the lower regions, when the cold of the evening comes on, it condenses, and falls on plants, and with its thick clammy substance stops the pores, and by that means prevents perspiration, and hinders the sap from ascending to nourish the flowers, shoots, &c.

Some say, That Mildew is a corrosive or nipping dew, proceeding from the vapours that are exhaled by the earth, which, being drawn up, and falling down again on the tender opening buds, infects them by its acrimony, and hinders the circulation of the nutritious sap in the proper vessels, upon which the leaves begin to fade, and the blossoms and fruit receive a very great prejudice.

There are others who make this observation, That the places most liable to Mildew are inclosed grounds and valleys, especially those that lie tending to the east; and the reasons that they give why those grounds which lie from the horizon to the east, are most subject to Mildew and blights, may be by the sun's attracting those vapours towards it, after the manner that a great fire in a room draws the air to it; so the sun having set these in motion, and not having strength enough to draw them into the middle region, to form them into a cloud, he does yet draw them till he be below the horizon, and then these dews tend to the

M I L

earth, from whence they were exhaled, and in motion to the west, do, as it were, fall upon the ground which lies eastward at right angles, and therefore is most offensive to them.

But I take the true cause of the Mildew appearing most upon plants which are exposed to the east, to proceed from a dry temperature in the air when the wind blows from that point, which stops the pores of plants, and prevents their perspiration, whereby the juices of the plants are concreted upon the surface of their leaves, which being of a sweetish nature, insects are incited thereto, where, finding proper nutriment, they deposit their eggs, and multiply so fast as to cover the whole surface of plants, and by their corroding the vessels, prevent the motions of their sap; and it is very probable, that the excrements of these insects may enter the vessels of plants, and by mixing with their juices, may spread the infection all over them; for it is observable, whenever a tree has been greatly affected by this Mildew, it seldom recovers it in two or three years, and many times is never entirely clear from it after.

Others suppose, That the reason why valleys afford more moisture than hills is, because of the dew which is attracted from the earth and herbs as before, and that they afford more moisture than hills (they say) is often seen by the mists, which are more frequent on them than on hills; this being drawn by the sun in the day time, and wanting wind to assist its motion, hangs in the lower region, and when the sun sets, it falls upon the plants with its thick clammy substance, and hinders the sap of the plant or tree from ascending to nourish its flowers or shoots, in those whose bark is tender and young, and the pores open with the heat of the season.

This dew has been observed in the great leaved Cherries, such as the Black Heart, the White Heart, &c. to fall upon them at the top, just at the beginning of the Midsummer shoot, which has so stopped the shoot that it has shot forth in other places below, and on the top of these shoots there have been many small flies feeding on this dew, which may plainly be seen and tasted on the leaves of Oak and Maple.

Some are of opinion, that Mildews and blights are the same thing; but others again, that Mildew is quite another thing than blights. They say Mildews are caused from the condensation of a fat and moist exhalation in a hot and dry summer, from the blossoms and vegetables, and also from the earth itself, which is condensed into a fat glutinous matter by the coolness and serenity of the air, and falls down on the earth again, part of which rests upon the leaves of the Oak and other trees, whose leaves are smooth, and for that reason do not so easily admit the moisture into them, as the Elm, and other rougher leaves do.

Other parts of Mildew rest upon the ears and stalks of Wheat, bespotting the same with a different colour from what is natural, being of a glutinous substance, by the heat of the sun, and it binds up so close the tender ears of Wheat, that it prevents the growth, and occasions it to be very light in the harvest.

Some are of opinion, that Mildews are the principal food of bees, it being sweet, and easily converted into honey.

MILIUM. Tourn. Inst. R. H. 514. tab. 298. Lin. Gen. Plant. 73. [so called of Mille, Lat. a thousand, because of the multitude of its grains.] Millet.

The CHARACTERS are,

It is of the Corn or Grass tribe, with one flower in each chaff, the chaff opening with two oval acute-pointed valves. The petal of the flower is bivalve, and smaller than the empalement. It hath three very short hairy stamens, terminated by oblong summits, and a roundish germen with two hairy styles, crowned by brush-shaped stigmas. The germen afterward turns to a roundish seed, covered by the petal of the flower.

M I L

This genus of plants is ranged in the second section of Linnæus's third class, which includes those plants whose flowers have three stamina and two styles.

The SPECIES are,

1. MILIUM (*Panicum*) paniculâ laxâ flaccidâ, foliorum vaginis pubescentibus. *Millet with a loose hanging panicle, and the sheaths of the leaves hairy.* Miliun semine luteo. C. B. P. 26. *Millet with a yellow seed.* Panicum Miliaceum. Lin. Sp.
2. MILIUM (*Sparsum*) paniculâ sparsâ erectâ, glumis aristatis. *Millet with a loose erect panicle, and bearded chaff.* Miliun paniculâ amplâ erectâ sparsâ. Houst. MSS. *Millet with a large, erect, sparsed panicle.*
3. MILIUM (*Effusum*) floribus paniculatis dispersis. Flor. Succ. 55. *Millet with dispersed flowers.* Gramen sylvaticum paniculâ miliacâ sparsâ. C. B. P. 3. *Wood Grass with a sparsed Millet-like panicle.*
4. MILIUM (*Confertum*) floribus paniculatis confertis. Prod. Leyd. 57. *Millet with panicles of flowers growing in clusters.* Gramen paniculatum Alpinum, latifolium, paniculâ miliacâ sparsâ. Scheu. Gr. 34. *Broad-leaved, Alpine, Panicle Grass, with a sparsed Millet-like panicle.*

The first sort grows naturally in India, but is now cultivated in many parts of Europe as an esculent grain; this rises with a Reed-like stalk from three to four feet high, and is channelled; at every joint there is one Reed-like leaf, which is joined on the top of the sheath, which embraces and covers that joint of the stalk below the leaf; this sheath is closely covered with soft hairs, but the leaf which is expanded has none; that has several small longitudinal furrows running parallel to the midrib. The top of the stalk is terminated by a large loose panicle, which hangs on one side, having a chaffy flower, which is succeeded by a small round seed, which is often made into puddings, &c. There are two varieties of this, one with white, and the other hath black seeds, but do not differ in any other particular.

This plant is ranged under the title of Panicum, by Linnæus, but as it is more generally known by its former appellation, so I chuse to continue it.

The second sort was discovered growing naturally at La Vera Cruz; this has a slenderer stalk than the former, which rises about three feet high. The sheaths which surround it have no hairs, but are channelled. The leaves are shorter than those of the former. The panicle stands erect, and the chaff has shorter awns, or beards.

The other two sorts grow naturally in woods, and are never cultivated in the fields, so do not require any farther description.

The common Millet was originally brought from the Eastern countries, where it is still greatly cultivated, from whence we are furnished annually with this grain, which is by many persons greatly esteemed for puddings, &c. but is seldom cultivated in England in quantity, but by way of curiosity in small gardens, for feeding of poultry; but the seeds generally ripen very well.

They must be sown the beginning of April, upon a warm dry soil, but not too thick, because these plants divide into several branches, and should have much room; and when they come up, they should be cleared from weeds, after which they will, in a short time, get the better of them, and prevent their future growth. In August these seeds will ripen, when it must be cut down, and beaten out, as is practised for other grain; but when it begins to ripen, if it be not protected from birds, they will soon devour it.

MILLEFOLIUM. See ACHILLEA.

MILLERIA. Houst. Gen. Nov. Martyn. Cent. 4. Lin. Gen. Plant. 881.

The CHARACTERS are,

This hath a compound flower, composed of several florets, and one half floret, which are included in one common empalement of one leaf, which is cut into three parts, and is permanent. The hermaphrodite florets have one tubulous petal, which is erect, and indented at the brim in

M I L

five parts; these have five hairy stamina, with erect linear summits connected in their middle, to the side, and are the length of the petal, and an oblong narrow germen, supporting a slender style, crowned by two narrow, obtuse, spreading stigmas; these florets are barren. The female half florets is of one leaf, stretched out on one side like a tongue, and is indented at the top; this hath a large three-cornered germen, supporting a slender style, crowned by two long bristly stigmas. The germen afterward turns to an oblong, three-cornered, obtuse seed, inclosed in the empalement.

This genus of plants is ranged in the fourth section of Linnæus's nineteenth class, which includes those plants with compound flowers, whose hermaphrodite flowers are barren, and the female flowers are fruitful.

The SPECIES are,

1. MILLERIA (*Quinquesflora*) foliis cordatis, pedunculis dichotomis. Hort. Cliff. 426. *Milleria with heart-shaped leaves, and forked stalks.* Milleria annua, erecta, major, foliis conjugatis, floribus spicatis luteis. Houst. MSS. *Greater, upright, annual Milleria, with leaves growing by pairs, and yellow spiked flowers.*
2. MILLERIA (*Maculata*) foliis infimis cordato-ovatis acutis rugosis, caulibus lanceolato-ovatis, acuminatis. *Milleria whose lower leaves are oval, heart-shaped, acute-pointed, and rough, and the upper ones oval, spear-shaped, and pointed.* Milleria annua erecta ramosior, foliis maculatis, profundius serratis. Martyn. Dec. 5. *Upright, annual, branching Milleria, with spotted leaves deeply sawed.*
3. MILLERIA (*Biflora*) foliis ovatis, pedunculis simplicissimis. Hort. Cliff. 425. *Milleria with oval leaves, and single foot-stalks.* Milleria annua erecta minor, foliis parietariæ, floribus ex foliorum alis. Houst. MSS. *Smaller, upright, annual Milleria, with a Pellitory leaf, and flowers proceeding from the wings of the leaves.*
4. MILLERIA (*Triflora*) foliis ovato-lanceolatis acuminatis trinerviis, pedunculis alaribus trifloris. *Milleria with oval, spear-shaped, acute-pointed leaves, having three veins, and foot-stalks proceeding from the wings of the leaves, with three flowers.* Milleria annua erecta, foliis parietariæ longioribus, floribus ex foliorum alis. Edit. Prior. *Annual erect Milleria, with a longer Pellitory leaf, and flowers proceeding from the wings of the leaves.*

The first sort was discovered by the late Dr. William Houstoun, at Campeachy, in the year 1731, from whence he sent the seeds to Europe; and as the characters which distinguish the genus, were different from all the other genera of the class to which it belongs, so he constituted a new genus with this title.

This rises with an herbaceous branching stalk from four to five or six feet high, garnished with heart-shaped leaves about four inches long, and three inches broad toward their base, drawing to a point at the end, which are slightly sawed on their edges, having two veins on each side the midrib, which diverge and join to it near the base, meeting again at the point, which generally is oblique to the foot-stalk. The leaves are of a light green, and hairy, standing opposite; their foot-stalks are about an inch long, and have a part of the leaf running on each side like wings. The stalks divide upward into forks, and the foot-stalks of the flowers come out at the divisions; these branch again by pairs, and terminate in loose spikes of yellow flowers; composed of four or five hermaphrodite florets, which are barren, and one female half floret, which is succeeded by a single, oblong, angular seed, wrapped in the empalement of the flower. It flowers in July and August, and the seeds ripen in autumn.

The second sort was discovered by Mr. Robert Millar, at Campeachy, in the year 1734; this approaches near to the first sort, but the stalks rise six or seven feet high, branching out very wide. The leaves are seven inches long, and four inches and a half broad toward their base, ending in long acute points; they are deeper sawed on their edges, and have several large

large black spots scattered over them; their surface is rougher, and they are of a darker green than those of the first. The upper leaves are long and spear-shaped; the foot-stalks of the flowers branch out wider, and the spikes of flowers are shorter than those of the first.

The third sort was discovered at Campeachy by the late Dr. Houstoun; this is also an annual plant, which rises with an herbaceous stalk upward of two feet high, branching out at a small distance from the root into three or four slender stalks, which are naked almost to the top, where they have two oval spear-shaped leaves placed opposite, which are about two inches long, and three quarters of an inch broad near their base, ending in points; they are hairy, and stand upon naked foot-stalks near an inch long, and are rough, having three longitudinal veins, and are slightly indented on their edges. The flowers come out at the foot-stalks of the leaves, in small clusters; the common empalement is composed of three orbicular leaves, which are compressed together; in each of these are situated two hermaphrodite florets, which are barren, and one female half floret, which is fruitful, being succeeded by a roundish angular seed, inclosed in the empalement. This flowers and perfects seeds about the same time with the former.

The fourth sort was discovered by the late Mr. Robert Millar, at Campeachy; this is an annual plant, which rises with an upright stalk three or four feet high, garnished the whole length with oval spear-shaped leaves near four inches long, and almost two broad near their base; they have three longitudinal veins, and toward the top there are two more which diverge from the midrib, but join again at the point. The upper side of the leaves are of a dark green and smooth, their under sides are of a pale green, and indented on their edges. The flowers grow from the wings of the leaves in small clusters, having three hermaphrodite and one female flower in each, standing upon short foot-stalks; these have empalements like the former, but they are much smaller. This flowers and seeds later in the year than either of the former, so that unless the plants are brought forward in the spring, they will not ripen their seeds in England.

The seeds of these plants should be sown early in the spring, on a moderate hot-bed; and when the plants are come up about two inches high, they should be each transplanted into a separate pot filled with light rich earth, and plunged into a moderate hot-bed of tanners bark, being careful to shade them from the sun until they have taken root, as also to water them frequently. After the plants are rooted, they should have a large share of free air admitted to them, by raising of the glasses of the hot-bed every day when the weather is warm, and in hot weather must be duly watered, for they are very thirsty plants. With this management, the plants will, in a month after transplanting, rise to a considerable height; therefore they should be shifted into larger pots, and placed in the stove, plunging them into the bark-bed, where they may have room to grow, especially the first and second sorts, which usually grow high and branch out where they are well managed. But the other sorts seldom rise above three or four feet high, and do not spread their branches very far, so these may be allowed less room.

In the middle of July these plants will begin to flower, and the seeds will be ripe about a month or six weeks after; therefore they must be gathered when they begin to change of a dark brown colour, otherwise they will soon fall off; especially those of the two large kinds, which will drop on the least touch when they are ripe. These plants will continue flowering till Michaelmas, or later, if the season proves favourable; but when the cold of the autumn comes on, they will soon decay.

MIMOSA A. Tourn. Inst. R. H. 605. tab. 375. Lin. Gen. Plant. 597. The Sensitive Plant.

The CHARACTERS are,

The empalement of the flower is small, of one leaf, indented in five parts at the top: the flower has one funnel-shaped petal, which hath five points. It hath many long hairy stamina, terminated by prostrate summits, and an oblong germen supporting a short slender style, crowned by a truncated stigma. The germen afterward turns to a long jointed pod with several transverse partitions, inclosing compressed seeds of various forms, and there are many male, female, and hermaphrodite flowers mixed in some of the species.

This genus of plants Dr. Linnæus has joined to the Acacia of Tournefort, and the Inga of Plumier, and places it in the first section of his twenty-third class, which includes those plants which have male, female, and hermaphrodite flowers on the same plant, which have many stamina and one style.

The SPECIES are,

1. MIMOSA (*Punetata*) inermis, foliis bipinnatis, spicis decandris, inferioribus castratis corollatis caule erecto tereti. Lin. Sp. 1502: Sensitive Plant without spines, double winged leaves, spikes having ten stamina, and the lower without stamina, and an erect taper stalk: Mimosa Jamaicensis. Zan. Hist. 144. Sensitive Plant of Jamaica.
2. MIMOSA (*Plena*) inermis, foliis bipinnatis, spicis pentandris, inferioribus plenis. Hort. Upsal. 145. Smooth Sensitive Plant with double winged leaves, the spikes with five stamina, and the under one double. Mimosa non spinosa, palustris & herbacea, procumbens, flore luteo pleno. Houst. MSS. Herbaceous, marsh, trailing Sensitive Plant without spines, and a double yellow flower.
3. MIMOSA (*Pernambucana*) inermis decumbens, foliis bipinnatis, spicis cernuis, pentandris, inferioribus castratis. Hort. Upsal. 145. Smooth Sensitive Plant with inclining stalks, double winged leaves, nodding spikes of flowers having five stamina, but the under ones without any. Mimosa spuria de Pernambuco, dicta mimosa Italica. Zan. Hist. 151. Spurious Sensitive Plant of Pernambuco, called Italian Sensitive Plant.
4. MIMOSA (*Pudica*) aculeata, foliis pinnatis. Prickly Sensitive Plant with winged leaves: Mimosa herbacea procumbens, & spinosa, caule tereti & villosa, filiquis articulatis. Houst. MSS. Trailing herbaceous Sensitive Plant having spines, with a taper and hairy stalk, and jointed pods.
5. MIMOSA (*Pudica*) foliis subdigitatis pinnatis, caule aculeata, hispido. Lin. Sp. 1501. Sensitive Plant with winged-banded leaves, a prickly declining stalk, and small pods growing in clusters, with prickly coverings. Mimosa humilis frutescens & spinosa, filiquis conglobatis. Plum. Cat. Low shrubby and prickly Sensitive Plant with clustered pods, commonly called the Humble Plant.
6. MIMOSA (*Quadrivalvis*) aculeata, foliis bipinnatis, caule quadrangulo, aculeis recurvis, leguminibus quadrivalvibus. Lin. Sp. Plant. 1508. Prickly Sensitive Plant with double winged leaves, a four-cornered stalk, recurved spines, and pods having four valves. Mimosa herbacea procumbens, & spinosa, caule quadrangulo, filiquis quadrivalvibus. Houst. MSS. Trailing and prickly herbaceous Sensitive Plant, with a quadrangular stalk, and pods having four valves.
7. MIMOSA (*Sensitiva*) foliis conjugatis pinnatis, partialibus bijugis, intimis minimis, caule aculeato. Lin. Sp. Plant. 1501. Sensitive Plant with conjugated winged leaves, whose wings have two pair of lobes, the inner of which are the least, and a prickly stalk. Mimosa spinosa prima, five Brasiliana latifolia, filiquis radiatis. Breyn. Cent. 1. 31. The first prickly, or broad-leaved Sensitive Plant of the Brazils, with radiated pods.
8. MIMOSA (*Asperata*) caule fruticoso, foliis bipinnatis, aculeatis, aculeis geminis, filiquis radiatis hirsutis. Fig. Plant. tab. 183. fol. 3. Sensitive Plant with a shrubby stalk, double winged prickly leaves, whose spines grow in pairs, and hairy radiated pods. Æschynomene spinosa quarta, five foliolis Acaciæ angustioribus, frondibus validissimas spinas habentibus. Breyn. Cent. 1. 43. The fourth prickly Sensitive Plant,

- Plant, with narrow *Acacia* leaves, armed with strong spines.
9. *MIMOSA* (*Viva*) inermis, foliis conjugatis pinnatis, partialibus quadrijugis subrotundis, caule inermi herbaceo. Lin. Sp. 1500. *Sensitive Plant with a creeping, herbaceous, unarmed stalk, conjugated winged leaves, and globular flowers proceeding from the wings of the stalks.* *Mimosa herbacea, non spinosa, minima, repens.* Sloan. Hist. Jam. 2. p. 58. *The least creeping herbaceous Sensitive Plant, having no spines.*
 10. *MIMOSA* (*Nilotica*) spinis stipularibus patentibus, foliis bipinnatis, partialibus extimis glandula interstinctis, spicis globosis pedunculatis. Hasselq. It. 475. *Acacia with double winged leaves, and globular spikes of flowers having foot-stalks.* *Acacia Aegyptica.* Hern. Mex. 866. *True Egyptian Acacia.*
 11. *MIMOSA* (*Farnesiana*) spinis stipularibus distinctis, foliis bipinnatis, partialibus octojugis, spicis globosis sessilibus. Hort. Upsal. 146. *Acacia Indica foliis, scorpioidis leguminosae, filiquis fuscis teretibus resinosis.* II. L. *Indian Acacia with taper resinous pods.*
 12. *MIMOSA* (*Cornigera*) spinis stipularibus geminis connatis, foliis bipinnatis. Hort. Cliff. 208. *Acacia with two spines joined at their base, and doubly winged leaves.* *Acacia similis Mexiocana, spinis cornu similibus.* *The great horned Acacia.*
 13. *MIMOSA* (*Unguis cati*) spinosa, foliis bigeminis obtusis. Hort. Cliff. 207. *Prickly Acacia with four obtuse leaves.* *Acacia quodammodo accedens, five Ceratonia & Acacia media Jamaicensis spinosa, bigeminatis foliis, flosculis stamineis, atronitente fructu, filiquis intortis.* Pluk. Phyt. *Acacia with branching leaves and twisted pods.*
 14. *MIMOSA* (*Arborea*) inermis, foliis bipinnatis, pinnis dimidiatis acutis, caule arboreo. Lin. Sp. 1503. *Tree Acacia without thorns, doubly winged leaves, whose pinnæ are acute.* *Acacia arborea maxima non spinosa, pinnis majoribus flore albo, filiqua contorta coccinea verticosa elegantissima.* Sloan. Jam. 157.
 15. *MIMOSA* (*Purpurea*) inermis, foliis conjugatis pinnatis, foliis intimis minoribus. Lin. Sp. 1500. *Purple Acacia without spines, conjugated winged leaves which are smallest below.* *Acacia Americana frutescens non aculeata, flore purpurascens.* Plum. Cat. *Shrubby American Acacia with thorns, and a purplish flower.*
 16. *MIMOSA* (*Houstoniana*) inermis, foliis bipinnatis glabris, pinnis tenuissimis, filiquis latis villosis. Fig. Pl. 5. *Acacia without thorns, doubly winged smooth leaves, whose pinnæ are very narrow, and broad hairy pods.* *Acacia Americana, non spinosa, flore purpureo, staminibus longissimis, filiquis planis villosis, pinnis foliorum tenuissimis.* Houst. MSS. *American Acacia without thorns, having purple flowers, with very long filaments, flat hairy pods, and very narrow leaves.*
 17. *MIMOSA* (*Lutea*) aculeata, foliis bipinnatis glabris, floribus globosis pedunculatis, aculeis longissimis. *Prickly Acacia with smooth doubly winged leaves, globular flowers having foot-stalks, and very long spines.* *Acacia spinosa, foliorum pinnis tenuissimis glabris, floribus globosis lutea, spinis longissimis.* Houst. MSS. *Prickly Acacia with very narrow smooth leaves, round yellow flowers, and very long thorns.*
 18. *MIMOSA* (*Glaucia*) inermis, foliis bipinnatis, partialibus sejugis, pinnis plurimis, glandula inter infima. Lin. Sp. Plant. 1502. *Acacia without thorns, doubly winged leaves, whose wings are separated, and have small glands between them.* *Acacia non spinosa, flore albo, foliorum pinnis latiusculis glabris, filiquis longis planis.* Houst. MSS. *White flowering Acacia without thorns, having broad smooth leaves, and long flat pods.*
 19. *MIMOSA* (*Angustissima*) inermis, foliis bipinnatis, pinnis angustissimis glabris, leguminibus tumidis. *Narrow-leaved unarmed Acacia, with doubly winged smooth leaves, and jointed pods.* *Acacia non spinosa, floribus globosis albis foliorum pinnis tenuissimis glabris, filiquis ad singula grana tumidis.* Houst. MSS. *Acacia without thorns, having round white flowers, with very narrow smooth leaves, and jointed pods.*
 20. *MIMOSA* (*Campeachiana*) spinosa, foliis bipinnatis, pinnis angustis, spinis singulis cornu bovinum per longitudinem fissum referentibus. *Acacia with doubly winged leaves having narrow pinnæ, and single spines like ox's horns split their length.* *Acacia spinosa tenuifolia, spinis singulis cornu bovinum per longitudinem fissum referentibus.* Houst. Cat. *Acacia with single thorns shaped like those of an ox's horn, and seem as if split thro' their length.*
 21. *MIMOSA* (*Cinerea*) spinis solitariis, foliis bipinnatis, floribus spicatis. Flor. Zeyl. 215. *Acacia with single spines, doubly winged leaves, and spiked flowers.* *Acacia spinosa tenuifolia, filiquis latis, spinis minimis recurvis solitariis.* Houst. Cat. *Prickly narrow-leaved Acacia with broad pods, and small recurved spines, which come out single.*
 22. *MIMOSA* (*Latifolia*) inermis, foliis conjugatis, pinnis terminalibus oppositis, lateralibus alternis. Lin. Sp. 1499. *Broad-leaved Acacia without thorns, conjugated leaves whose upper pinnæ are opposite, but the side ones are alternate.* *Acacia non spinosa, juglandis folio, flore purpurascens.* Plum. Sp. 17. *Acacia without thorns, Walnut-tree leaves, and a purple flower.*
 23. *MIMOSA* (*Circinalis*) aculeata, foliis conjugatis pinnatis, pinnis æqualibus, stipulis spinosis. Lin. Sp. 1499. *Prickly Acacia with conjugated winged leaves, which are equal, and prickly stipule.* *Acacia foliis amplioribus, filiquis circinatis.* Plum. Sp. 17. *Acacia with broad leaves and twisted pods.*
 24. *MIMOSA* (*Fagifolia*) inermis, foliis pinnatis bijugis petiolo marginato. Lin. Sp. 1498. *Broad-leaved Acacia without spines, whose wings have four lobes, and running foot-stalks.* *Arbor filiquosa, faginis foliis, Americana, floribus comosis.* Pluk. Phyt. tab. 141. fol. 2. The first sort grows naturally in most of the islands in the West-Indies, and it has been found growing in some warm moist spots, as far north as Virginia. This rises with upright branching stalks six or seven feet high, which become ligneous toward the root, but are not perennial (at least they are not so here in any situation, the plants always decaying in winter;) these are smooth, and garnished with double winged leaves, composed of four or five pair of long winged lobes, which have about twenty pair of small leaves ranged along the midrib; they are smooth and rounded at their points, of a full green on their upper side, but pale on their under. These small leaves contract themselves together on their being touched, but the foot-stalks do not decline at the same time, as those do which are titled Humble Plants, so this is called the Sensitive Plant by way of distinction. The flowers are produced upon long foot-stalks, which come out from the wings of the leaves, and are disposed in globular heads which nod downward; they are yellow, and all those which have petals have ten stamina in each, but those situated round the border have neither petals or stamina; those on the upper part of the spike are succeeded by pods an inch and a half long, and a quarter of an inch broad, which change to a dark brown when ripe, inclosing three or four compressed, shining, black seeds.
- The second sort was discovered by the late Dr. Houston at La Vera Cruz, growing in stagnant waters, where the stalks were very broad and flat, and floated on the surface, in the same way as the pond weeds do; but in those places where the water was dried up the stalks grew upright and were round, which is always the case when the plants are cultivated in gardens, so that they might easily pass for different plants, to those who never saw them growing in both situations. When this sort is cultivated in gardens, it has great resemblance to the first, but the stalks of this never grow so erect, the wings of the leaves are longer, and stand more horizontal; the heads of flowers are much larger, the stamina are longer, and the flowers on the under side of the spike which have no stamina are double: the pods of this sort are shorter, and much broader than those of the first sort. This is also an annual plant in this country. This sort was since discovered by a friend of mine, growing naturally

naturally in a marshy spot of land in the island of Barbuda, from whence he sent me the seeds, with a large branch of the plant, in a glass filled with a lixivium, which preserved it in the state it was gathered, with the flowers and pods upon it.

The third sort grows naturally in all the islands of the West-Indies, where it is titled the slothful Sensitive Plant, because the leaves do not contract on their being touched. The stalks of this sort seldom rise more than two feet and a half high, they are smooth, and garnished with double-winged leaves, composed of three or four pair of wings which are shorter, and the small leaves are much narrower than those of the two former sorts; the heads of flowers are smaller, and the pods are longer and narrower than those of the other. This sort will live through the winter in a moderate warm air.

The fourth sort was discovered by the late Dr. Houstoun, growing naturally at La Vera Cruz. This hath ligneous stalks which decline to the ground, spreading out two or three feet from the root, and send out several side branches, which are armed with short yellowish spines under the foot-stalks of the leaves, and are their whole length closely covered with bristly stinging hairs; the foot-stalks of the leaves are three inches long, and at the top sustain four single winged leaves, whose base meet in a point, but spread above like the fingers of an open hand. These wings are about three inches long, and are closely garnished with small narrow lobes, set by pairs along the midrib, which is also covered on the under side with the like bristly hairs as the stalk. The flowers come out from the wings of the leaves upon pretty long foot-stalks; they are collected into globular heads, and are of a pale yellowish colour; these are succeeded by small jointed pods, containing two or three shining black seeds.

The fifth sort is the most common of any in the islands of the West-Indies, as also in the English gardens; the seeds of this sort are frequently sold in the seed-shops, by the title of Humble Plant. The roots of this are composed of a great number of hairy fibres, which mat close together, from which come out several ligneous stalks which naturally decline toward the ground, unless they are supported; they are armed with short recurved spines, and garnished with winged leaves, composed of four, and sometimes five wings, whose base join at a point, where they are inserted to the foot-stalk, spreading upward like the fingers of a hand; these wings are shorter than those of the former sort, and the stalks are not hairy. The flowers come out from the wings of the stalks, upon short foot-stalks; they are collected in small globular heads, are yellow, and are succeeded by short, flat, jointed pods, which have two or three orbicular, bordered, compressed seeds in each: these pods are in close clusters, almost covered with stinging hairy covers.

The sixth sort grows naturally at La Vera Cruz, from whence the late Dr. Houstoun sent the seeds. This hath a perennial creeping root, which spreads and multiplies greatly in the sands, where it grows wild; the stalks are slender, and have four acute angles, armed with short recurved spines pretty closely; the leaves stand upon long prickly foot-stalks, which are thinly placed on the branches; they are composed of two pair of wings, standing about an inch asunder; the wings are short, and the small leaves are narrow, and not placed so close together, as in many of the other species. The foot-stalks of the flowers come out from the wings of the leaves, sustaining a small globular head of purple flowers; these are succeeded by four-cornered pods about two inches long, which have four cells, opening with four valves, containing several angular seeds in each.

This sort spreads so much at the root, as to render it not so productive of flowers and seeds as most of the others; and the plants which are propagated by parting of the roots, are always weak, so that the best way is to propagate them

by seeds, when they can be obtained. This is one of the sorts, whose foot-stalks fall on being touched.

The seventh sort grows naturally at La Vera Cruz, from whence the late Dr. Houstoun sent the seeds.

This rises with a slender ligneous stalk seven or eight feet high, armed with short recurved thorns. The leaves grow upon long foot-stalks which are prickly, each sustaining two pair of wings; the exterior pair have two lobes which join at their base, and are rounded on their outside, but strait on their inner edges, very much shaped like a pair of those shears used for shearing of sheep; these two outer pair of lobes are much larger than the inner; they are almost two inches long, and one broad in the middle. From the place where these are inserted to the stalk, come out small branches which have three or four globular heads of pale purple flowers coming out from the side, upon short foot-stalks, and the principal stalk has many of those heads of flowers on the upper part for more than a foot in length; and this, as also the branches, are terminated by the like heads of flowers: these are succeeded by broad, flat, jointed pods, which open with two valves, some having but one, others two, and some have three orbicular compressed seeds. The leaves of this sort move but slowly when they are touched, but the foot-stalks fall when they are pressed pretty hard.

The eighth sort was also found by the same gentleman, growing naturally at La Vera Cruz. This hath a shrubby erect stalk about five feet high, which is hairy, and armed with short, broad, strong thorns, which are white, standing on each side sometimes almost opposite, and at others alternately. The leaves are composed of five or six pair of wings, which are ranged opposite along a strong midrib, and between each pair are placed two short strong spines, pointing out each way. The small leaves which compose these wings are extremely narrow, and stand very close to each other. Toward the upper part of the stalk, the flowers are produced from the sides, upon short foot-stalks; they are collected into globular heads, and are of a bright purple colour; the stalks are also terminated by smaller heads of the like flowers. These are succeeded by flat jointed pods about two inches long, and a quarter of an inch broad, which spread open like rays, there being commonly five or six of these joined together at their base to the foot-stalk. These pods separate at each articulation, leaving the two side membranes or borders standing; and the seeds which are compressed and square, drop out from the joints of the pods; these pods are hairy at first, but as they ripen become smooth.

This is a perennial plant, which may be preserved through the winter in a warm stove, by which method the seeds may be obtained, for they seldom flower the first year. The foot-stalks of this sort do not fall on being touched, but the small leaves on the wings close up.

The ninth sort grows naturally in Jamaica; this hath trailing herbaceous stalks, which put out roots at every joint, which fasten in the ground and spread to a great distance, as they will also do here, when placed in a bed of tanners bark. I have had a single plant in one summer, which has spread near three feet square, whose branches were closely joined, so as to cover the surface of the bed; but when they are thus permitted to grow, they seldom produce flowers. These stalks have no thorns, but are garnished with winged leaves composed of two pair of short wings, whose small leaves or lobes are narrow; these stand upon short foot-stalks, which are smooth. The leaves of this sort contract and fall down upon the least touch, so that where the plant is extended to a distance, a person may draw any figure with a stick upon the leaves, which will be very visible till the leaves recover again. The flowers come out from the wings of the leaves, upon naked foot-stalks about an inch in length; they are of a pale yellowish colour, and are collected into small globular heads; these are succeeded by short, flat, jointed

Pods, containing three or four compressed roundish seeds.

These plants are all of them propagated by seeds, which should be sown early in the spring, upon a good hot-bed. If the seeds are good, the plants will appear in a fortnight or three weeks, when they will require to be treated with care, for they must not have much wet till they have acquired strength; nor should they be drawn too weak, so that fresh air should be admitted to them at all times when the air is temperate. In about a fortnight or three weeks after the plants come up, they will be fit to transplant, especially if the bed in which they were sown, continues in a proper degree of heat; then there should be a fresh hot-bed prepared to receive them, which should be made a week before the plants are removed into it, that the violent heat may be abated before the earth is laid upon the dung, and the earth should have time to warm before the plants are planted into it. Then the plants must be carefully raised up from the bed to preserve the roots entire, and immediately planted in the new bed, at about three or four inches distance, pressing the earth gently to their roots; then they should be gently sprinkled over with water, to settle the earth to their roots; after this they must be shaded from the sun till they have taken new root, and the glasses of the hot-bed should be covered every night to keep up the heat of the bed. When the plants are established in their new bed, they must have frequent, but gentle waterings; and every day they must have free air admitted to them, in proportion to the warmth of the season, to prevent their being drawn up weak; but they must be constantly kept in a moderate degree of heat, otherwise they will not thrive. In about a month after the plant will be strong enough to remove again, when they should be carefully taken up, preserving as much earth to their roots as possible, and each planted in a separate small pot, filled with good kitchen-garden earth, and plunged into a hot-bed of tan, carefully shading them from the sun till they have taken new root; then they must be treated in the same manner as other tender exotic plants from very warm countries.

The sorts which grow upright and tall, will soon rise high enough to reach the glasses of the hot-bed, especially if they thrive well; therefore they should be shifted into larger pots, and removed into the stove, and if they are plunged into the tan-bed there, it will greatly forward them. The first sort will often flower here, if the plants are raised early in the spring, and brought forward by their removal from one hot-bed to another; and two or three times I have had their seeds ripen, but this can only be expected in very warm seasons.

The perennial sorts will live through the winter, if they are preserved in a warm stove, and the following summer they will produce flowers and ripen their seeds. Some of these may be propagated by laying down their branches, which will put out roots, and then may be separated from the old plants; and I have sometimes propagated them by cuttings, but the plants which rise from seeds are preferable to either of these.

There is no particular management which these plants require, different from others of the same warm countries; the great care must be to keep them in a proper temperature of heat, and not to give them too much water, especially in cool weather; nor should they be kept too dry, for many of the sorts require frequent waterings, as they naturally grow in moist places. There should also be care taken that they do not root into the tan-bed, for they soon put out their roots through the holes at the bottom of the pots, which, when they strike into the tan, will cause the plants to grow very luxuriant; but when they are removed, and these roots are cut or broken off, the plants seldom survive it; therefore the pots should be frequently drawn out of the tan, and if any of the roots are beginning to get through the holes at the bottom, they should be cut off close; and when the

roots are very closely matted together, they should be turned out of the pots, and pared round to reduce them, and then potted again, either in pots of the same size, or if the plants require, in pots one size larger; but they must not be over-potted, for then the plants will not thrive.

Some of those sorts whose stalks spread near the ground, may be turned out of the pots in the middle of June, and planted in a very warm border, where, if they are covered with bell or hand-glasses, they will live through the summer; but these will not grow very large, and upon the approach of cold in the autumn, they are soon destroyed: however, those who have not conveniency of stoves or tan-beds, may raise the plants on common hot-beds in the spring; and when they have acquired strength, they may be treated in this manner, whereby they will have the pleasure of these plants in summer, though not in so great perfection, as those who have the advantages before-mentioned: but these plants will not thrive in the open air in this country, nor will they retain their sensibility when they are fully exposed to the air.

It would be to little purpose to trouble the reader with the several idle stories related of these plants by travellers, nor to insert what has been said by others, who have attempted to account for the motion of the leaves of these plants on their being touched, since there has not been any thing wrote on this subject, worthy of being noticed, that I have yet seen; I shall therefore only mention what I have myself observed in these plants, for more than forty years that I have cultivated them.

The first is, that they are more or less susceptible of the touch or pressure, according to the warmth of the air in which they grow; for those plants which are kept in a warm stove, contract their leaves immediately on being touched, either with the hand, a stick, or any other thing, or by the wind blowing upon them: some of the sorts only contract their small leaves, which are placed along the midrib; others not only contract their small leaves, but the foot-stalk also declines downward on being touched: the first are called Sensitive, and the second Humble Plants; but when these plants are placed in a cooler situation, they do not move so soon, nor contract so closely, as those which are in a greater warmth; and those which are entirely exposed to the open air, have very little motion, but remain in one state, neither expanded nor closed, but between both, especially in cool weather; nor do these shut themselves at night, as those do which are in a warm temperature of air.

The second is, that it is not the light which causes them to expand, as some have affirmed, who have had no experience of these things; for in the longest days of summer, they are generally contracted by five or six in the evening, when the sun remains above the horizon two or three hours longer; and although the glasses of the stove in which they are placed, is covered close with shutters to exclude the light in the middle of the day, yet if the air of the stove is warm, the leaves of the plants will continue fully expanded, as I have several times observed. Nor do these plants continue shut till the sun rises in the morning, for I have frequently found their leaves fully expanded by the break of day in the morning; so that it is plain the light is not the cause of their expansion, nor the want of it that of their contraction.

I have also observed, that those plants which are placed in the greatest warmth in winter, continue vigorous, and retain their faculty of contracting on being touched; but those which are in a moderate warmth, have little or no motion.

When any of the upper leaves of these plants are touched, if they fall down and touch those which are below them, it will occasion their contracting and falling, so that by one touching another, they will continue falling for some time. When the air of the stove in which these plants stand, is in a proper temperature of warmth, the plants will recover themselves, and their leaves will be fully expanded in about eight or

or ten minutes. I have frequently watched them as they have been recovering, and have always found it has been by a vibratory motion, like the index of a clock.

Some of the sorts are so susceptible of the touch, that the smallest drop of water falling on their leaves will cause them to contract, but others do not move without a much greater pressure.

The roots of all the sorts have a very strong disagreeable odour, almost like that of a common sewer. I have met with some accounts of these plants, in which it is mentioned, that the leaves and branches have a poisonous quality, and that the Indians extract a poison from them, which kills by slow degrees, and that the root of the plant is the only remedy to expel it; but how far this is true I cannot say, having never made any experiments on the qualities of these plants; but if these plants are endowed with so deadly a quality as related, this sensibility with which they are endued, may be designed by providence to caution persons from being too free with it; and as many of them are strongly armed with thorns, so that is a guard against their being eaten by animals; for in all the enquiries which I have made of those persons who have resided in the countries where they naturally grow, I could never learn that any animal will browse upon them.

These plants are all of them natives of America, so were unknown to the other parts of the world till that was discovered, for I have not heard of any of them being found in any other country: and a few years ago I sent some of the seeds of these plants to China, which succeeded, and occasioned great admiration in all who saw the plants.

The Acacias are so nearly allied to the Mimosas in their characters, that Linnæus has joined them in the same genus; and as his system is now generally followed, so in compliance with that I have done the same.

The tenth sort of Acacia is the tree from whence the true Succus Acaciæ is taken, and the Gum Arabic exudes from the branches of the same; which, though mentioned as a native of Egypt, yet it is also found in divers parts of America, from whence the seed of this tree have been sent into England, and there raised in several gardens near London.

This tree arrives to a large size in the countries where it grows, but in England is rarely seen more than eight or ten feet high. It frequently flowers in autumn, but never produces any seeds.

The eleventh sort is the most common kind in Jamaica and Barbadoes, and the other warm parts of America; and, for the sweetness of its flowers, has been dispersed through most parts of Europe; and though a native of the warmer parts of the Indies, it hath been made familiar to the Italian gardens, and is cultivated likewise in great plenty in Portugal and Spain.

The Italian gardeners, who bring over Orange-trees, &c. every year, generally bring also many young plants of this sort to England, under the title of Gazia; but as they are too tender to live in a common green-house in England, so few of those which are purchased of them succeed.

I have had some plants of this sort upwards of sixteen feet high, which have produced great numbers of flowers in July and August, but these were kept in a stove in winter, and in glass-cases in summer, to screen them from wet and the cold, for they will not flower in the open air in this country. The flowers are of a bright yellow colour, and smell sweet; in the West-Indies it is called Sponge-tree.

The twelfth sort is at present very rare in England, and only to be found in some curious gardens. This tree produces its spines by pairs, which are extreme large and crooked, and of a whitish colour; but I do not remember ever to have seen this flower.

In England, from the dried samples however, which I have received from Campeachy, with many flowers upon them, there appears but little beauty in them; nor do the trees in their native soil make a better ap-

pearance, their branches always growing deformed; and being but thinly garnished with leaves; when in their greatest vigour; but for several months they are destitute of leaves, so that the only thing remarkable in this tree is, the uncommon wreathed spines with which the trunk and branches are fully beset. These have the resemblance of animal horns; and are variously twisted and contorted.

The twenty-third sort was brought from the Bahama Islands by Mr. Catesby, anno 1726. The seeds of this plant (which are flat, and one half of a beautiful red colour; the other half of a deep black) grow in long twisted pods, opening when the seeds are ripe, on one side, and letting them out, which hanging by a small thread for some time out of the pods, make a very agreeable appearance; the leaves of this tree branch out and divide into many ramifications: the lobes are roundish, and placed in a very regular order. The flowers have not as yet appeared in England, but from a painting done from the plant in the country, they seem to be very beautiful.

The thirteenth sort was brought from Jamaica, and is growing in the physic-garden at Chelsea; this hath four large lobes to each leaf; the spines are short, stiff, and crooked; and the seeds grow in twisted pods like the former. This plant is well described in Sir Hans Sloane's Natural History of Jamaica: By the inhabitants of America it is called Doctor Long; under which name, the seeds are frequently brought to England.

Most of the other sorts here mentioned, were collected by the late ingenious Dr. William Houstoun, in Jamaica, at Vera Cruz and Campeachy, who sent the seeds of most of them into Europe; many of which are now growing in the physic-garden at Chelsea, where some of them have produced flowers and plenty of seeds.

These being all tender, are to be placed in stoves in the winter, and in summer must be but a short time exposed to the open air, and have a warm situation.

They are propagated by sowing their seeds on a hot-bed in the spring of the year, which will in a short time appear above ground, and in about five or six weeks after, be fit to transplant, when a fresh hot-bed is to be prepared for them, and should be pretty warm; the next thing to be provided is a quantity of small halfpenny pots, which are to be filled with fresh, light, sandy earth; these should be plunged into the hot-bed, but not into dung; for if these beds are made with warm horse dung, they ought to be covered with earth as deep as the pots, whose bottoms should rest upon the dung, for otherwise the roots of the plants may suffer by too much heat; but beds of tanners bark seldom heat so violently. As soon as the earth in the pots is warm, which will be in two or three days, you should carefully take up the young plants out of the first hot-bed, planting four or five plants into each of these pots, giving them a gentle watering to settle the earth to their roots, and screening them with mats over the glasses from the heat of the sun, until they have taken root; after which time you must give them air, by raising the glasses in proportion to the heat of the weather, or to the constitution of the plants.

The tenth, eleventh, and twelfth, sorts are very tender, especially while young, therefore should have a hot-bed of tanners bark; and as they increase in bulk, should be shifted into bigger pots. The earth for these should be a little lighter, and more inclined to a sand, than for the other sorts; but never plant them in pots that are too large, which is full as bad to these as to Orange-trees; neither give them too much water, especially in winter. The tenth sort being the hardiest of the three, will, when grown to be woody, stand in a common stove, which should be kept to the point of temperate heat in winter; and in the summer time, in warm weather, may enjoy the open free air: but the eleventh and twelfth sorts must have a bark-stove in winter; nor should they be exposed to the open air in summer, at least for four

or five years, until they are grown very woody, for they are very tender, and with great difficulty preserved in this climate. The stove in which these should be placed in winter, must be kept above the temperate point, as marked in the botanical thermometers. These should have very little water in winter, but in summer time will require frequent refreshings, though at that season it should not be given them in great quantities at one time. The eleventh sort is a very beautiful tree. The twelfth sheds its leaves just before the new ones come on, so that it is naked of leaves about a month or six weeks in the spring of the year, which has occasioned some people to throw them away as dead, when, if they had let them remain, they would have come out fresh again. This I thought proper to mention, in order to caution people not to be too hasty in throwing out trees for dead, but preserve them through the succeeding summer, to see if they will shoot again; for I have known several plants, which, after having been given over by unskilful persons for dead, have the July following shot out vigorously again; and others, which have died to the surface of the earth, have risen again from the root.

The three sorts of horned Acacias are very often destitute of leaves for two or three months, appearing to have no life; but they will put out fresh leaves towards autumn, which is commonly the season when they are most vigorous. These should be exposed in the summer season for about two months, to clear them from insects, which greatly infest them, in a place defended from strong winds; and in the winter they require a moderate degree of warmth.

All the other sorts here mentioned are propagated by seeds, which, seldom ripening in this country, must be procured from America, particularly at Campeachy, where there is great variety of this tree, many sorts of which have been hitherto unknown to botanical writers. In bringing over the seeds of these trees, they should be taken out of the pods when gathered, and put up in papers, and ought to have Tobacco, or some other noxious herb, put between the papers, to keep off insects, otherwise the seeds will be eaten and destroyed before they arrive in England. For the insects deposit their eggs in small punctures which they make in the pods; and as these are soon hatched, so they immediately attack the seeds for food, and eat holes through them, by which they are spoiled from growing. This has often happened to seeds which have been sent me from America.

There are several of these Acacias, which are very tender while they are young; but, after two or three years growth, become hardy enough to bear the open air in summer, though scarce any of them will live through the winter in a green-house, unless they have some warmth in very cold weather.

Acacia Germanorum. See PRUNUS SYLVESTRIS.

Acacia Virginiana. See ROBINIA.

Acacia, the Three-thorned. See GLEDITSIA.

MIMULUS. Lin. Gen. Plant. 761. Cynorrhynchium. Mitch. 3.

The CHARACTERS are,

The flower hath an oblong, prismatical, permanent empalement of one leaf; it is of the lip or ringent kind, having one petal, whose tube is the length of the empalement, and the brim is divided into two lips. The upper lip is erect, divided at the top into two parts, which are reflexed on their side; the lower lip is broad and trifid, the middle segment is the least; the palate is convex and bifid. It has four slender stamina, two longer than the other, terminated by bifid kidney-shaped summits, and a conical germen supporting a slender style, crowned by an oval, bifid, compressed stigma. The germen afterward turns to an oval capsule with two cells, filled with small seeds.

This genus of plants is ranged in the second section of Linnæus's fourteenth class, which includes those plants whose flowers have two long and two short stamina, and their seeds are included in the capsule.

We know but one SPECIES of this genus at present in England, viz.

MIMULUS (*Ringens*) erectus, foliis oblongis linearibus sessilibus. Hort. Upsal. 176. tab. 2. *Upright Mimulus with oblong linear leaves sitting close to the stalk. Digitalis perfoliata glabra, flore violaceo minore.* Mor. Hist. 2. p. 479. *Smooth perfoliated Foxglove, with a small Violet flower.*

This plant grows naturally in North America in moist ground. It has a perennial root and an annual stalk, which decays in the autumn; the stalk is square, and rises a foot and a half high, garnished at each joint with two oblong smooth leaves, which are broadest at their base, where they almost join round the stalk, but end in acute points. The lower part of the stalk sends out two or three short branches, and the upper part is adorned with two flowers at each joint, coming from the bosom of the leaves on each side the stalk; these have an oblong curved empalement with five angles, indented at the top into five parts, out of which arises the flower, with a long curved tube, spreading open at the top into two lips, the upper lip standing erect, which is slightly cut into two parts at the top; the under lip turns downward, and is cut into three slight segments. The flowers are of a Violet colour, but have no scent. These appear in July, and are succeeded by oblong capsules with two cells, filled with small seeds, which in warm seasons ripen in the autumn.

This plant is very hardy in respect to cold, but should have a loamy soft soil, rather moist than dry, and not too much exposed to the sun. It may be propagated by parting of the roots in the autumn, but the slips should not be divided too small; it may also be propagated by seeds, which should be sown in autumn, soon after they are ripe, for those which are sown in the spring seldom grow the same year: these may be sown on a border exposed to the morning sun, and the plants may be afterward planted in the flower-garden.

MINT. See MENTHA.

MIRABILIS. Lin. Gen. Plant. 215. Jalapa. Tourn. Inst. R. H. 129. tab. 50. Marvel of Peru, or Four o'Clock Flower.

The CHARACTERS are,

The empalement of the flower has five, oval, spear-shaped, small leaves, and is erect, swelling, and permanent. The flower has one funnel-shaped petal, with a slender tube sitting upon the nectarium, which spreads open above, and is cut into five obtuse segments. It hath five slender stamina, which adhere to the petal, which are unequal and inclined, terminated by roundish summits, with a roundish germen within the nectarium, supporting a slender style, crowned by a globular stigma. The germen afterward becomes an oval five-cornered nut, inclosing one seed.

This genus of plants is ranged in the first section of Linnæus's fifth class, which includes those plants whose flowers have five stamina and one style.

The SPECIES are,

1. MIRABILIS (*Jalapa*) floribus congestis terminalibus erectis. Lin. Sp. Plant. 252. *Marvel of Peru, with bunches of flowers erect, terminating the stalk. Admirabilis Peruviana.* Clus. Hist. 2. p. 87.

2. MIRABILIS (*Dichotoma*) floribus sessilibus axillaribus erectis solitariis. Amœn. Acad. 4. p. 267. *Marvel of Peru, with an erect single flower sitting close to the wings of the branches.* Jalapa officinarum. Mart. Cent. 1. f. 1. *The then supposed Jalap of the shops.*

3. MIRABILIS (*Longiflora*) floribus congestis terminalibus longissimis nutantibus, foliis subvillosis. Act. Holmœn. 1756. p. 176. *Long-flowered Marvel of Peru, whose flowers are in bunches, terminating the stalks and nodding, with hairy leaves.* Mirabilis Mexicana. Hern. Mex. 170. f. 2.

The first sort is the Marvel of Peru, which has been many years cultivated in the English gardens for ornament; of this there are several varieties, which differ in the colour of their flowers; two of these retain their difference, one of them has purple and white flowers, which are variable, some of them are plain purple, others are plain white, but most of them are variegated with the two colours; and all these varie-

ties are frequently upon the same plant, and at others on different plants; the other has red and yellow flowers, which are generally mixed in the same flowers, but are often with plain flowers of both colours on the same plant, intermixed with those which are variegated; but some plants have only plain flowers; and I have never found that the seeds of the purple and white sort, ever produced the yellow and red, nor the latter ever vary to the former, and I have constantly cultivated both more than forty years; but although these do not change from one to the other, yet as there is no other difference between them than in the colour of their flowers, I have not enumerated them as distinct species.

The second sort is very common in all the islands of the West-Indies, where the inhabitants call it the Four o'Clock Flower, from the flowers opening at that time of the day. Of this sort I have never seen any with variable flowers; they are of a purplish red colour, and not much more than half the size of the other. The stalks of this sort have thick swollen joints; the leaves are smaller, and the fruit is very rough, so there can be no doubt of their being distinct species, for I have never seen any alteration in this from seed, and I have cultivated it many years. Tournefort was informed by Father Plumier, that the root of this plant was the officinal Jalap, upon which he constituted the genus, and gave that title to it; but the late Dr. Houstoun was fully informed in the Spanish West-Indies of the contrary, and brought over a drawing of the plant which was made by a Spaniard at Halapa, and he carried two or three of the plants to Jamaica, where he planted them in a garden, but after he left the island they were destroyed by hogs: however, he was fully satisfied of its being a *Convolvulus*, which Mr. Ray had many years before given the Jalap the title of, but upon what authority it does not at present appear. Some few years after I received three seeds of the Jalap from the Spanish West-Indies, one of which grew, and became a large plant, having a bulbous root, as large as those of the Jalap which are imported, but the plant produced no flowers in the three years it lived; and in the winter 1739-40 it died, since when I have not been able to procure any seeds; however, I am fully satisfied that the Jalap is a species of *Convolvulus*: indeed the roots of the Marvel of Peru are purgative, and when given in a double quantity for a dose, will answer the purpose of Jalap.

The third sort was sent from Mexico a few years since. The seeds of this were first sent me from Paris, by Dr. Monier, of the Royal Academy of Sciences, and afterward I had some sent me from Madrid, by Dr. Hortega. The stalks of this sort fall on the ground, if they are not supported; these grow about three feet long, and divide into several branches, which are garnished with heart-shaped leaves, placed opposite; these, as also the stalks, are hairy and viscous, sticking to the fingers of those that handle them. The flowers come out at the end of the branches; they are white, and have very long slender tubes, and a faint musky odour; these are like the other sorts, closely shut all the day, but expand every evening when the sun declines. The seeds of this sort are larger than those of any other species, and are as rough as those of the second sort.

The two varieties of the first sort are very ornamental plants in gardens, during the months of July, August, and September; and if the season continues mild, they often last till near the end of October. The flowers do not open till toward the evening, while the weather continues warm, but in moderate cool weather, when the sun is obscured, they continue open almost the whole day. The flowers are so plentifully produced at the ends of the branches, as that when they are open, the plants seem entirely covered with them, and there being some plain, and others variegated on the same plants, they make a fine appearance. The plants are propagated by seeds, in the choice of which there should be care taken not to save any

from those plants whose flowers are plain; and those who are desirous of having only the variegated kinds, are careful to pull off all the plain flowers from those plants which they intend for seeds, to prevent them from bearing any seeds; by this method they rarely have any plants with plain flowers.

The seeds should be sown on a moderate hot-bed in March, and when the plants come up, they should have plenty of air admitted to them, when the weather is mild, to prevent their being drawn up weak; and when they are about two inches high, they should be transplanted on another very moderate hot-bed; or if they are each planted in a small pot filled with light earth, and plunged into a moderate hot-bed, it will be a more secure way, for then there will be no danger in shaking them out of the pots, when they are to be planted in the borders, so as to preserve all the earth to their roots; by this method, they will not require to be shaded, whereas those that are to be transplanted from the second hot-bed to the borders, often rise with little earth to their roots, so must be carefully shaded, otherwise they often miscarry.

When they are in the second hot-bed, they should be shaded till they have taken fresh root, after which they must have plenty of free air admitted to them to prevent their being drawn up weak, and in May they must be gradually inured to the open air. The beginning of June, if the season is favourable, they should be transplanted into the borders of the pleasure-garden, giving them proper room, and after they have taken new root, they will require no further care. If these seeds are sown in a warm border the beginning of April, they will grow very well, but the plants will be late in the season before they flower.

As the seeds of these plants ripen very well every year, so there are not many who are at the trouble of preserving their roots; but if these are taken out of the ground in autumn, and laid in dry sand all the winter, secured from frost, and planted again in the spring, they will grow much larger, and flower earlier than the seedling plants: or if the roots are covered in winter with tanners bark to keep out the frost, they may remain in the borders, provided the soil be dry. If the roots which are taken out of the ground, are planted the following spring in large pots, and plunged into a hot-bed, under a deep frame, they may be brought forward, and raised to the height of four or five feet, as I have frequently practised; and these plants have come earlier in the season to flower, so have been intermixed with other ornamental plants, to decorate halls and shady courts, where they have appeared very beautiful.

The other two species require the same treatment, but the second sort is not quite so hardy as the other two, so unless the plants are brought forward in the spring, they will not flower till very late, so their seeds will not ripen.

MISLETOE. See *VISCUM*.

MITELLA. Tourn. Inst. R. H. 241. tab. 126. Lin. Gen. Plant. 496. [so called of Mitella, Lat. a little mitre, because the seed-vessel of this plant resembles a bishop's mitre.] Bastard American Sanicle.

The CHARACTERS are,

The flower has a bell-shaped empalement of one leaf, cut into five points, which is permanent. It hath five petals, ending in many hairy points, and are inserted in the empalement, as are also the ten awl-shaped stamina, which are shorter than the petals, and terminated by roundish summits. It hath a roundish germen, which is bifid, with scarce any style, crowned by two obtuse stigmas. The empalement afterward becomes an oval capsule with one cell, opening with two valves, filled with small seeds.

This genus of plants is ranged in the second section of Linnæus's tenth class, which contains those plants whose flowers have ten stamina and two styles or stigmas.

The SPECIES are,

1. MITELLA (*Diphylla*) *scapo diphylla*. Lin. Gen. Nov. 29. *Mitella with flower-stalks having two leaves.* Mitella

M O L

tella Americana, florum petalis fimbriatis. Tourn. Inst. 242. *American Mitella with fringed petals to the flowers.*

2. MITELLA (*Nuda*) scapo nudo. Amœn. Acad. 2. p. 252. *Mitella with a naked stalk.*

The first sort grows naturally in the woods, in most parts of North America. It has a perennial root, from which come out many heart-shaped angular leaves, some of which are obtuse, and others end in acute points; they are indented on their edges, and of a lucid green, a little hairy, and stand upon pretty long foot-stalks. The flower-stalks arise immediately from the root, having two or three angular leaves toward the bottom, and about the middle of the stalk come out two small leaves with acute angles, placed opposite. The stalks rise eight or nine inches high, and are terminated by a loose spike of small whitish flowers, whose petals are fringed on their edges; these appear the beginning of June, and are succeeded by roundish capsules filled with small seeds.

The second sort grows naturally in the northern parts of Asia; this is of a humbler growth than the first, seldom rising more than five or six inches high. The leaves are not so angular as those of the first sort, and the flower-stalks are always naked, having no leaves. The spikes of flowers are shorter, and more compact.
